# CRITICAL COMPILATION OF SCALES OF SOLVENT PARAMETERS. PART I. PURE, NON-HYDROGEN BOND DONOR SOLVENTS 

(Technical Report)<br>Prepared for publication by<br>J.-L. M. ABBOUD AND R. NOTARIO<br>Instituto de Química Física 'Rocasolano’, CSIC, c/Serrano 119, E-28006 Madrid, Spain

Membership of the working party: T. Abe (Japan), M. H. Abraham (UK), E. Bosch (Spain), E. Buncel (Canada), J.-F. Gal (France), J. I. García (Spain), G. Gritzner (Austria), I. Koppel (Estonia), E. M. Kosower (Israel), C. Laurence (France), Y. Marcus (Israel), J. A. Mayoral (Spain), M. Rosés (Spain), J. Shorter (UK).

[^0]
# Critical compilation of scales of solvent parameters. Part I. Pure, non-hydrogen bond donor solvents (Technical Report) 

## INTRODUCTION AND FUNDAMENTAL CONCEPTS

It has long been known [1] that solvents often affect chemical reactivity, this involving, e.g. the shift of the position of chemical equilibria (thermodynamic aspect) as well as significant changes in reaction rate constants (kinetic aspect). Physical properties, particularly the frequencies and intensities of transitions in IR, UV-visible, fluorescence, NMR and ESR spectroscopies are also known to be affected by solvents.

These phenomena are consequences of differences in the solvation of reagents and products (thermodynamic effects) or reagents and activated complexes (kinetic effects). Differential solvation of species in the ground and excited states accounts for the spectral phenomenology indicated above [1,2]. Differences in solvation of a given solute in two different solvents determine the size of the corresponding partition coefficient.

It is customary to state that these effects reflect the influence of 'solvent polarity'. According to Reichardt [1a] 'solvent polarity' is 'the overall solvation capability (or solvation power) of solvents, which in turn depends on the action of all possible, nonspecific and specific intermolecular interactions between solute ions or molecules and solvent molecules, excluding, however, those interactions leading to definite chemical alterations of the ions or molecules of the solute (such as protonation, oxidation, reduction, chemical complex formation, etc.)'.

This definition underscores the extreme complexity of 'solvation effects' at the molecular level. This notwithstanding, solvent effects (SE) often display some remarkable regularities that allow in many cases an 'empirical treatment' that sheds light on their origin and main contributors.

Consider a solute $\Sigma$ and two different properties $P_{1}$ and $P_{2}$, taking the values $\left\{P_{10}, P_{11}, \ldots, P_{1 i}, \ldots\right\}$ and $\left\{P_{20}, P_{21}, \ldots, P_{2 i}, \ldots\right\}$, respectively, in solvents $\mathrm{S}_{0}, \mathrm{~S}_{1}, \ldots, \mathrm{~S}_{i}, \ldots$ A scale of SEs is simply constructed by taking for each solvent, $\mathrm{S}_{i}$, the difference $P_{1 i}-P_{10}, S_{0}$ being chosen as a reference solvent. If the property $P_{1}$ is a 'good descriptor' of SEs on $P_{2}$, eqn 1 holds for solvent $\mathrm{S}_{i}$ :
$P_{2 i}-P_{20}=k\left(P_{1 i}-P_{10}\right)$
or
$P_{2 i}-P_{20}=k p_{i}$
wherein $k$ is a constant independent of the solvents and determined solely by $P_{2} . p_{i}$ is the 'solvent parameter' characteristic of solvent $S_{i}$.

More generally, the properties being compared might belong to two different solutes.
For any property $P_{m}$ of any solute, and if $P_{1}$ is a 'good descriptor', eqn 3 holds:
$P_{m i}-P_{m 0}=k_{m} p_{i}$
We draw attention to the (frequently overlooked) fact that if equations such as (3) were truly general, then, all SEs would be linearly related to an extremely high degree of precision and a single, universal scale of SEs would exist. This is against all the available experimental evidence. Excellent correlations of narrower scope do exist however, that successfully link a very large amount of experimental data for a substantial variety of solvents and solutes and a relatively small number of empirical scales.

In this compilation, scales are selected on the basis of criteria to be discussed below. For each of them, the most reliable values of solvent parameters are given. The physical foundations and the scope of the scales are discussed. Some suggestions regarding their use are made. For the purpose of facilitating future work in the field, some indications are given regarding the experimental determination of the various parameters.

Solvent-solute interactions always involve dispersion or London's forces [3-6] and, very often, dipolar and/or multipolar interactions [7,8]. Current theoretical models including London's, Hildebrand's [9-11] and/or reaction field (RF) [8,12] theories allow to express these 'non-specific' parts of SEs as functions of physical properties such as the refractive index, relative permittivity and thermodynamic properties of the solvent.

Quantitative rankings of solvents ('solvent scales') can thus be constructed on the basis of such properties as the refractive index, $n$; electric permittivity (formerly known as dielectric constant), $\varepsilon_{\mathrm{r}}$; Hildebrand's solubility parameter, $\delta_{H}$; the modulus of the molecular dipole moment, $\mu$, and various functions thereof. These scales shall be termed 'model-independent'. Quite generally, it is assumed that dispersive and electrostatic interactions are independent and additive. Following Palm and Koppel, [13,14] it is further assumed that other contributions to solvent-solute interactions, notably hydrogen bonding are also independent from and additive to, the 'non-specific' contributions.

Use is often made of 'model-dependent' scales. They are based on the similarity principle [15]: the ranking of the efficiency of solvents on a given property is quantitatively compared to their influence on a reference physical or chemical property of a reference solute ('molecular probe'). The associated formalism is quite simple and has been outlined above. These scales can be divided into two different categories, depending on whether they quantify the overall 'polarity effect' of the solvent, in Reichardt's sense or else, they are intended to measure one or various components of the overall solvation power of the solvent.

Some scales have been built on the basis of a statistical treatment of SEs on large sets of experimental data of various origins. They are absolutely 'empirical' in that they try to quantify 'average' SEs without specifically seeking a formal link with current theoretical concepts on solvent-solute interactions.

Last we mention that the case of self-associated solvents and mixtures thereof involves a number of conceptual and experimental difficulties that, in our opinion, justify a separate treatment.

Here we deal with nonhydrogen bond donor solvents, although a number of weak hydrogen bond donor solvents are also included.

Part I of this compilation is organized as follows:

- Description of the Tables.
- Physical properties and model-independent scales.
- Table 1.
- Model-dependent scales:
- (a) 'Overall solvation' scales.
- (b) Scales of dipolarity/polarizability.
- (c) Scales of hydrogen bonding accepting power (hydrogen bonding basicity).
- (d) Scales of 'hard' and 'soft' Lewis acidity and basicity.
- Statistical scales.
- Table 2.
- General comments on the scales.

## DESCRIPTION OF THE TABLES

Data are presented for 346 solvents and the gas phase. For each of them, the Chemical Abstracts Registry Number as well as the official (IUPAC) and eventually, common names are given, together with the values for the following physical properties: refractive index $(n)$, relative permittivity $\left(\varepsilon_{\mathrm{r}}\right)$, modulus of the molecular dipole moment $(\mu)$ and functions thereof, molar weight $(M)$, density at $25.0^{\circ} \mathrm{C}\left(d^{25}\right)$, molar volume at $25.0^{\circ} \mathrm{C}\left(V_{\mathrm{m}}\right)$, standard molar vaporization enthalpies and energies at $298.15 \mathrm{~K}, \Delta_{\text {vap }} H^{\circ}$ and $\Delta_{\text {vap }} U^{\circ}$, and Hildebrand's solubility parameter $\left(\delta_{\mathrm{H}}\right)$. Model-dependent scales are given next. These scales are based on data obtained by physical methods. In all instances the original data, e.g. IR or UV-visible
frequencies of absorption maxima are given in the original units and/or in energy units. The importance of this point has been particularly emphasized by Kosower [16]. 'Normalized values' are also given when available. In cases wherein scales are constructed using experimental data for several indicators or molecular probes, both the actual data and the averaged parameters are given for each indicator. This is intended to avoid blurring any specific solute-dependent effects, however, small [17]. 'Single parameter scales' giving an overall quantification of SEs according to Reichardt's concept are given first. They are followed by several specific scales of 'dipolarity-polarizability' effects, hydrogen-bonding basicity and Lewis' 'hard' and 'soft' acidity and basicity. Last, representative 'statistical' scales intended to quantify general or specific solvent effects are presented.

It should be kept in mind that this is only a compilation of scales of parameters of solvent effects, that is, a tool. In no case is this work intended to be a monograph on solvent effects or even on scales of solvent effects. The final choice of the magnitudes and scales to be tabulated was made taking into consideration the advice of the various members of the working party. Because of space limitations, not all their suggestions could be followed.

The choice of the scales given in this compilation is, by its very nature, somewhat arbitrary and oversights are therefore possible. Our main guidelines were as follows:

1 The compilation had to present those physical data known to be of primary importance in most current theoretical models and correlation analysis treatments of solvent effects.

2 All empirical scales widely used over the years as well as others, however recent, that provide data for large sets of solvents had to be included.

3 As regards specific scales, as many well-identified solvent-solute interactions as possible had to be covered. For each of these scales, the criteria of widespread use and potential usefulness were taken into consideration.

4 In general, simple physical properties of the bulk solvents and parameters determined by means of standard physical techniques or based on readily available data were preferred.

## DEFINITION, UNITS AND SOURCES OF PHYSICAL PROPERTIES AND MODEL-INDEPENDENT SCALES.

## Physical properties

Symbols and units are taken from the Second Edition of the IUPAC manual on Quantities, Units and Symbols in Physical Chemistry [18]. The main sources of information are: (i) the Beilstein database [19] and the original publications reported therein; (ii) the fourth edition of Riddick, Bunger \& Sakano's Organic Solvents. Physical Properties and Methods of Purification [20], (iii) the three volumes of McClellan's Tables of Experimental Dipole Moments [21-23], (iv) the 1994 review by Laurence, Abboud and co-workers [17a] and the Doctoral Thesis of M. T. Dalati [17b], (v) Majer \& Svoboda's Enthalpies of Vaporization of Organic Compounds. A critical review and data compilation [24]. The values reported in the present tabulation have been averaged over the available experimental data whenever values from different sources and seemingly comparable quality were at hand.

## The refractive index

The refractive index $n$ is the ratio of the velocity of light in the vacuum to the velocity of light in a particular substance [25]. It is a dimensionless magnitude. In this compilation, refractive indexes are for the sodium-D doublet (average vacuum wavelength 589.6 nm ) whenever possible. If not, values for 'white light' are given. In view of this, refractive indexes are labeled $n$ instead of $n_{\mathrm{D}}$. Because of the availability of data, a standard temperature of $20.0^{\circ} \mathrm{C}$ was selected. When necessary, the value was obtained by interpolation from data at other temperatures. Notice that in general, refractive indexes can be experimentally determined to within $2 \times 10^{-4}$ to $2 \times 10^{-5}$. In fact, when comparing data for the same solvent, at the same temperature and wavelength as determined by different groups, differences one hundred to one thousand times this value are found. Under the circumstances, $n$-values are consistently given here with four significant figures.

## The relative permittivity (formerly known as dielectric constant)

The relative permittivity, $\varepsilon_{\mathrm{r}}$, is a measure of the effect a solvent has on the force with which two oppositely charged plates attract each other. The reference is the attraction in vacuum. $\varepsilon_{\mathrm{r}}$ is dimensionless. Experimental values are also given at $20.0^{\circ} \mathrm{C}$. When necessary and warranted by the availability of data at other temperatures, the value at $20.0^{\circ} \mathrm{C}$ was determined by interpolation. In principle, $\varepsilon_{\mathrm{r}}$ values can be determined experimentally to within 0.001 . However, here again, and whenever comparisons can be carried out, the agreement between data from different laboratories is often much worse: in the range $0.01-0.1$. Notice that [17a] and [17b] report one of the largest sets of $\varepsilon_{\mathrm{r}}$ values determined in the same laboratory.

## Modulus of the molecular dipole moment, $\mu$

Given a distribution of electric charges $Q_{i}, \boldsymbol{r}_{i}$ being the corresponding distance vectors to a reference point, $\boldsymbol{\mu}=\Sigma Q_{i} r_{i}$ [26]. The SI unit is $C \mathrm{~m}$. In practice, use is often made of the debye unit, D . $1 \mathrm{D}=3.33564 \times 10^{-30} \mathrm{C} \mathrm{m}$. It is unfortunate that no homogeneous set of physical state and experimental methods could be found that applies to all the solvents of this compilation. Under the circumstances, values determined in the gas phase, particularly by microwave spectroscopy were preferred. In the absence of gas phase data, values for solutions in hexane, cyclohexane, tetrachloromethane and benzene (in this order) were chosen. Even in the gas phase, disagreements between values determined by different groups by nonspectroscopic methods are substantial, often in the $0.1-0.2 \mathrm{D}$ range. As regards solution values, even larger discrepancies are not uncommon. Whenever the solute is made out of molecules involved in conformational equilibria (as in the case of 1,2-dichloroethane, $\mathrm{ClCH}_{2}-\mathrm{CH}_{2} \mathrm{Cl}$ ) temperature and/or medium can strongly affect the value of the observed dipole moment. In these cases, the use of this magnitude for the quantitative treatment of medium effects cannot be encouraged.

## Functions of $n$ and $\varepsilon_{r}$

The use of these functions is based on fundamental concepts of reaction field (RF) [8,12] theory as applied to electrostatic and dispersive interactions. $\mathrm{f}(n)$ and $\mathrm{g}(\mathrm{r})$ are defined through eqns (4) and (5):
$f(n)=\left(n^{2}-1\right) /\left(n^{2}+1\right)$
$g\left(\varepsilon_{\mathrm{r}}\right)=\left(\varepsilon_{\mathrm{r}}-1\right) /\left(\varepsilon_{\mathrm{r}}+1\right)$
These and cognate functions are widely used in Correlation Analysis treatments of medium effects. Let $\delta n, \delta \varepsilon_{\mathrm{r}}$, $\delta f$ and $\delta g$ stand for the estimated uncertainties on $n, \varepsilon_{\mathrm{r}}, f(n)$ and $g\left(\varepsilon_{\mathrm{r}}\right)$. Equations 6a and 6b are readily derived from eqns 4 and 5 .

$$
\begin{align*}
& \delta f(n) / f(n) \sim(4 n \delta n) /\left(n^{2}+1\right)\left(n^{2}-1\right)  \tag{6a}\\
& \delta g\left(\varepsilon_{\mathrm{r}}\right) / g\left(\varepsilon_{\mathrm{r}}\right) \sim\left(2 \delta \varepsilon_{\mathrm{r}}\right) /\left(\varepsilon_{\mathrm{r}}+1\right)\left(\varepsilon_{\mathrm{r}}-1\right)
\end{align*}
$$

In view of the orders of magnitude of $n, \varepsilon_{\mathrm{r}}, \delta n$ and $\delta \varepsilon_{\mathrm{r}}$, eqns 6 a and 6 b yield estimates of $\delta f(n) / \mathrm{f}(n)$ and $\delta g\left(\varepsilon_{\mathrm{r}}\right) / \mathrm{g}\left(\varepsilon_{\mathrm{r}}\right)$ of $\sim 1-2 \times 10^{-3}$. Values of $f(n)$ and $g\left(\varepsilon_{\mathrm{r}}\right)$ are thus given with three decimal figures. The difference $\left[g\left(\varepsilon_{\mathrm{r}}\right)-f(n)\right]$ has also a theoretical foundation and is related to orientation polarization. For molecules devoid of a permanent dipole moment, Maxwell's equation, $\varepsilon_{\mathrm{r}}=n^{2}$, holds. This expression involves the value of the refractive index extrapolated to a frequency such that no orientation polarization occurs any longer but, nevertheless low enough to include the contributions of the electronic and atomic polarizations [27]. The values of the refractive index given here are not extrapolated and therefore small differences, in the range $0.01-0.02$ cannot be considered significant.

## Relative density at $25^{\circ} \mathrm{C}$ [28]

The relative density at $25^{\circ} \mathrm{C}\left(d^{25}\right)$ is defined as the ratio of the density (mass density) of the solvent at $25^{\circ} \mathrm{C}$ to that of water at $4^{\circ} \mathrm{C}$. It is a dimensionless quantity.

## Molar mass [29]

The molar mass, $M$ is defined as $M=m / n . m$ is the mass of a sample, and $n$ is the amount $n=N / L$ where $N$ is the number of atoms or molecules and $L$ is the Avogadro-Loschmidt constant. The SI unit is $\mathrm{kg} / \mathrm{mol}$. In this compilation, for practical reasons, values are given in $\mathrm{g} / \mathrm{mol}$.

Molar volume at $25^{\circ} \mathrm{C}$ [29]
The molar volume at $25^{\circ} \mathrm{C}\left(V_{\mathrm{m}}{ }^{25}\right)$ [29] is defined as the volume of one mole of the liquid at $25^{\circ} \mathrm{C}$. SI units are $\mathrm{m}^{3} / \mathrm{mol}$. For practical reasons, values are given in $\mathrm{cm}^{3} / \mathrm{mol}$.

## Standard molar enthalpy of vaporization at 298.15 K

The standard molar enthalpy of vaporization at 298.15 K is noted $\Delta_{\text {vap }} H^{\circ}$. It has been defined as the difference between the molar enthalpy of the ideal gas at a standard pressure and that of the saturated liquid at 298.15 K . [30] $\Delta_{\text {vap }} H^{\circ}$ is given by eqn 7 :
$\Delta_{\text {vap }} H^{\circ}=H^{\circ}(\mathrm{g})-H\left(\mathrm{I}, \mathrm{p}_{\text {sat }}\right)=\Delta_{\text {vap }} H-\int_{0}^{\mathrm{p}_{\text {sat }}}\left[V^{\mathrm{g}}-T\left(\partial V^{\mathrm{g}} / \partial T\right)_{\mathrm{p}}\right] \mathrm{d} p$
The selected standard pressure is $10^{5} \mathrm{~Pa}$ or 0.1 MPa . As indicated in [30], the enthalpy and internal energy of an ideal gas are pressure-independent and the choice of the standard state has no influence on $\Delta_{\text {vap }} H^{\circ}$ values. $\Delta_{\text {vap }} H$ stands for the enthalpy of vaporization of the liquid at the reference temperature and is defined as the difference between the enthalpies of the vapor and liquid phases at this temperature and at the corresponding saturated vapor pressure, $p_{\text {sat }}$, eqn 8:
$\Delta_{\text {vap }} H=H\left(g, p_{\text {sat }}\right)-H\left(l, p_{\text {sat }}\right)$
$\Delta_{\text {vap }} H^{\circ}$ can be written as in eqn 12:
$\Delta_{\text {vap }} H^{\circ}=\Delta_{\text {vap }} H+\left[H^{\circ}(g)-H\left(g, p_{\text {sat }}\right)\right]$
The last term in eqn 9 is the standard departure function representing the difference between the enthalpies of the ideal gas and the saturated vapor. This term is always positive and increases with the temperature. According to [24], at temperatures more than $100^{\circ} \mathrm{C}$ below the boiling point this term is always less than $0.1 \%$ of $\Delta_{\text {vap }} H$ and can be generally neglected.

Both terms in eqn 9 contribute to the overall uncertainty on $\Delta_{\text {vap }} H^{\circ}$. The uncertainty on $\Delta_{\text {vap }} H$ is that associated with the experimental determination of this quantity. In general, it is in the range $0.1-3 \mathrm{~kJ} / \mathrm{mol}$. The uncertainty on the second term, whenever significant (see above) originates in the ancillary PVT information needed to carry out the pressure correction as well as on the type of compound and the method used to compute the correction. According to a comparative study by Majer \& Svoboda [30], for a given compound the uncertainty increases with the temperature but is essentially independent of the method. Except for extremely volatile solvents, the leading source of uncertainty for the majority of the materials considered in this compilation is that originating in $\Delta_{\text {vap }} H$.
$\Delta_{\text {vap }} H^{\circ}$ values are defined as the standard molar enthalpies of vaporization at 298.15 K . The data presented here were taken from [24] whenever possible. Majer \& Svoboda have classified the data according to their quality. When data from this source were not available, the Beilstein database was used. We have not attempted to judge the quality of the latter data according to the criteria of [24]. Instead, we consider that a value of $2.0 \mathrm{~kJ} / \mathrm{mol}$ is a conservative value that covers the combined uncertainties on these values.

## Standard internal energy of vaporization or cohesive energy

The standard internal energy of vaporization or cohesive energy is noted $\Delta_{\text {vap }} U^{\circ}$ and its formal definition is given by eqn 10a:
$\Delta_{\text {vap }} U^{\circ}=U^{\circ}-U_{\text {sat }}^{1}$
That is $\Delta_{\text {vap }} U^{\circ}$ is the difference between the energy of the ideal gas at a standard pressure and that of the saturated liquid at this temperature [24] and pressure. Equation 10 b follows from this definition:
$\Delta_{\text {vap }} U^{\circ}=\Delta_{\text {vap }} H^{\circ}-R T$
$\Delta_{\text {vap }} U^{\circ}$ has a fundamental physical meaning as it measures the energy necessary to bring the entities (molecules or atoms) of the liquid from their equilibrium distances to an infinite distance.

Fundamental reference texts on the experimental determination and general study of $\Delta_{\text {vap }} U^{\circ}$ are Majer \& Svoboda's compilation [24] as well as Barton's Handbook of Solubility Parameters and Other Cohesion Parameters [11].
$\Delta_{\text {vap }} U^{\circ}$ values are obtained from the corresponding enthalpies $\Delta_{\text {vap }} H^{\circ}$ through eqn (10b). The latter, in turn, are determined from $\Delta_{\text {vap }} H$. It follows that numerical uncertainties on cohesion energies are the
same as for the standard enthalpy of vaporization at $298.15 \mathrm{~K} . \Delta_{\text {vap }} U^{\circ}$ is obtained immediately from $\Delta_{\text {vap }} H^{\circ}$.

## Cohesive energy density

The quantity $\Delta_{\text {vap }} U^{\circ} / V_{\mathrm{m}}$ plays a key role in the theory of regular solutions [9-11]. It measures the cohesive energy per unit of volume and is termed 'cohesive energy density'. Following Hildebrand, [911] its square root $\left(\Delta_{\text {vap }} U^{\circ} / V_{\mathrm{m}}\right)^{1 / 2}$ is represented by $\delta$. Here, the notation $\delta_{\mathrm{H}}$ (for 'Hildebrand's delta') is used in order to avoid possible confusions. $\delta_{\mathrm{H}}$ is generally known as the 'solubility parameter'. Barton's monograph [11] is a leading reference on the subject.

The values presented here were calculated using the appropriate $\Delta_{\text {vap }} U^{\circ}$ and $V_{\mathrm{m}}$ data also given in this compilation.

The ratio $\Delta_{\text {vap }} U^{\circ} / V_{\mathrm{m}}$ has the dimensions of a pressure. Thus, $\delta_{\mathrm{H}}$ has the dimensions of (pressure) ${ }^{1 / 2}$ and the formal SI unit is $\mathrm{Pa}^{1 / 2}$. On account of the order of magnitude of the $\delta_{\mathrm{H}}$ values, $\mathrm{MPa}^{1 / 2}$ units are more convenient [11] and shall be used here.
(A comment on notations: pages $650-651$ of the text, and eqns $7-10$ closely follow [24]. The notations, however, are different. This is so because they have been adapted to the more recent norms of [18]).

(a) Chemical Abstracts Registry Number of the solvent; (b) Refractive index of the solvent, measured at $20.0^{\circ} \mathrm{C}$, unless noted otherwise. All values taken from [17a], unless noted otherwise; (c) Relative permittivity of the solvent measured at $20.0^{\circ} \mathrm{C}$, unless noted otherwise. All values taken from [17a], unless noted otherwise; (d) Molecular dipole moment of the solvent measured in the gas phase unless noted otherwise. All values in Debye units, taken from [21-23], unless noted otherwise; (e) Function of the refractive index of the solvent defined through the equation $f(n)$ $=\left(n^{2}-1\right) /\left(n^{2}+1\right)$. See text; (f) Function of the relative permittivity of the solvent defined through the equation $g\left(\varepsilon_{\mathrm{r}}\right)$ $=\left(\varepsilon_{\mathrm{r}}-1\right) /\left(\varepsilon_{\mathrm{r}}+1\right)$. See text; (g) Difference between the function $g\left(\varepsilon_{\mathrm{r}}\right)$ and $f(n)$; (h) Values taken from [19] and the original publications reported therein; (i) Value taken from Catálogo de Química Fina 1994-1995, from Aldrich; (j) Values taken from [20]; (k) Value measured in cyclohexane solution; (l) Value measured as 'pure' liquid; (m) Value measured in tetrachloromethane solution; (n) Value measured in benzene solution; (o) Value measured in n-heptane solution; (p) Value taken from [17b]; (q) Value measured in n-hexane solution; (r) Estimated value, taken from [17b]; (s) Value measured in dioxane solution; (t) 1.13 and 1.36D are the values corresponding to the N -gauche and N -cis forms, respectively; (u) 0.66 and 0.80 D are the values corresponding to the axial and equatorial forms, respectively.

(a) Molar mass of the solvent, in $\mathrm{g} / \mathrm{mol}$; (b) Relative density of the solvent, at $25^{\circ} \mathrm{C}$, unless noted otherwise. It is a dimensionless magnitude. All values taken from ref. [20], unless noted otherwise. (c) Molar volume of the solvent at $25^{\circ} \mathrm{C}$, in $\mathrm{cm}^{3} / \mathrm{mol}$; (d) Standard enthalpy of vaporization of the solvent at 298.15 K , in $\mathrm{kJ} / \mathrm{mol}$. All values taken from [24], unless noted otherwise; (e) Standard internal energy of vaporization of the solvent at 298.15 K , in $\mathrm{kJ} / \mathrm{mol}$; (f) Cohesive energy density of the solvent in $\mathrm{Mpa}^{1 / 2}$; (g) Values taken from [19] and the original publications reported therein; (h) Value taken from Catálogo de Química Fina 1994-1995, from Aldrich. Temperature is not given. (i) Value taken from [20].

## DEFINITION, UNITS AND SOURCES OF MODEL-DEPENDENT SCALES

## ‘Overall solvation’ scales

$E_{T}(30)$ and $E_{T}^{N}$
These are possibly the most widely used empirical solvent 'polarity' scales. According to Reichardt [1,3], the $E_{\mathrm{T}}(30)$ value for a specified solvent is defined as the molar transition energy (in $\mathrm{kcal} / \mathrm{mol}$ ) for the long wavelength electronic transition of dye 1a, 2,6-diphenyl-4-(2,4,6-triphenylpyridinio)-phenolate as a solution in this solvent at $25.0^{\circ} \mathrm{C}$ and at a pressure of $0.1 \mathrm{MPa} . E_{\mathrm{T}}(30)$ is obtained from the experimentally determined vacuum wavelength of the absorption maximum of this transition ( $\lambda_{\max }$ ) through eqn (11): $E_{\mathrm{T}}(30) /(\mathrm{kcal} / \mathrm{mol})=28591 /\left(\lambda_{\max } / \mathrm{nm}\right)$

The long-wavelength intramolecular charge-transfer absorption band ('solvatochromic band' [1]) exhibits very large hypsochromic shifts with increasing solvent 'polarity' (in Reichardt's sense).

1a is very sparingly soluble in solvents of low polarity. This has prompted Reichardt and co-workers to develop other indicators endowed with higher solubility in these media. The much more lipophilic penta-tert-butyl-substituted derivative $\mathbf{1 b}$ has been found to be quite satisfactory for the purpose of extending the $E_{\mathrm{T}}(30)$ scale to these solvents (Scheme 1). The quantitative link between $E_{\mathrm{T}}(30)$ and $E_{\mathrm{T}}(\mathbf{1 b})$ is given by eqn [12]:
$E_{\mathrm{T}}(\mathbf{1 b}) /(\mathrm{kcal} / \mathrm{mol})=0.9424 E_{\mathrm{T}}(30) /(\mathrm{kcal} / \mathrm{mol})+1.808$
with $n=57 ; r=0.9990 ; \mathrm{u}=0.17 \mathrm{kcal} / \mathrm{mol}$

1a, $R=H ; 1 b, R=t-B u$.
1a,b
Scheme 1

Equation (12) allows the indirect estimation of the $E_{\mathrm{T}}(30)$ values for low polarity solvents.
'Primary' $E_{\mathrm{T}}(30)$ values, that is, those obtained directly from the study of the electronic absorption spectrum of 1a are generally known within $0.1 \mathrm{kcal} / \mathrm{mol}$. Simple statistical considerations indicate that 'secondary' values, obtained through eqn 12 are affected by an uncertainty of $\sim 2 \times 0.17=0.34 \mathrm{kcal} / \mathrm{mol}$.

The $E_{\mathrm{T}}(30)$ values given in this compilation come from two main sources: (i) Reichardt's 1994 review [3] and (ii) Reichardt \& Schäfer's [31a] 1995 paper. The latter contains new data as well as some revised values for selected hygroscopic solvents. We emphasize that the absorption spectra of DimrothReichardt's dyes such as $\mathbf{1 a}$ and $\mathbf{1 b}$ are known to be extremely sensitive to traces of water and other
hydrogen bond donor impurities [32]. Data for super-critical $\mathrm{CO}_{2}$ are from very recent work by Reichardt and co-workers [31b].
$E_{\mathrm{T}}{ }^{\mathrm{N}}$ is a dimensionless 'normalized' scale, defined through eqn 13:
$E_{\mathrm{T}}{ }^{\mathrm{N}}($ Solvent $)=\left[E_{\mathrm{T}}(\right.$ Solvent $\left.)-E_{\mathrm{T}}(\mathrm{TMS})\right] /\left[E_{\mathrm{T}}(\right.$ Water $\left.)-E_{\mathrm{T}}(\mathrm{TMS})\right]$
wherein tetramethylsilane (TMS) and water are selected as rather extreme cases of 'polarity'. The values given in this compilation are taken from the same sources as $E_{\mathrm{T}}(30)$.
(Regarding the use of the term solvatochromism. According to Reichardt [1]: 'The term solvatochromism is used to describe the pronounced change in position (and sometimes intensity) of an UV-Visible absorption band, accompanying a change in the polarity of the medium.... This term is widely used. Some experts in the field, notably Kosower, disagree with its use. Thus, he states [16] that: '[solvatochromism]...does not properly reflect the spirit of the probe, which is to probe the microenvironment, be it glass, solid, surface or solvent. I suggest that we change this word to perichromism. ..').

## $Z$ (and $Z^{\prime}$ )

The $Z$ scale is due to Kosower [33] and has been widely used. It is based on the high solvent-sensitivity of the frequency of the charge-transfer absorption band of the indicator 1-ethyl-4-carbomethoxypyridinium iodide (2a). This band undergoes a substantial bathochromic shift with increasing solvent 'polarity'. The value of $Z$ for a given solvent is defined as the molar transition energy (in $\mathrm{kcal} / \mathrm{mol}$ ) for the long wavelength electronic transition of dye 2 , as a solution in this solvent at $25.0^{\circ} \mathrm{C}$ and at a pressure of $0.1 \mathrm{MPa} . Z$ is also obtained through an expression similar to eqn (11), from the experimentally determined wavelength of the absorption maximum of this transition $\left(\lambda_{\max }\right)$.

The values presented in this compilation are mostly taken from Kosower's original publications [3335] and from the review by Griffiths \& Pugh [36] in which values from Pugh's Doctoral Thesis are given [37]. Data from other sources [38-47], are also given. Notice that, in general, data from different origins agree within 0.1 or $0.2 \mathrm{kcal} / \mathrm{mol}$. However, in some cases, particularly in solvents of low polarity, large differences (of up to $5 \mathrm{kcal} / \mathrm{mol}$ ) are observed. They likely originate in traces of acidic impurities (including water).

Kosower [33] also examined the behavior of the longest wavelength transition in the electronic absorption spectrum of 4-cyano-1-ethylpyridinium iodide (2b) (Scheme 2). Medium effects on the corresponding transition energies are linearly related to $Z$-values to a very high degree of correlation [48] and a standard deviation of $0.5 \mathrm{kcal} / \mathrm{mol}$. Marcus [48] suggested the use of the symbol $Z^{\prime}$ for the scale of medium effects based on the solvatochromic shifts undergone by the longest wavelength band in the electronic absorption spectrum of $\mathbf{2 b}$. We report here the experimental values of $Z^{\prime}$ taken from [45] as well as those given in [48] and determined by means of the correlation between $Z$ and $Z^{\prime}$. For the former, uncertainties are in the range $0.1-0.2 \mathrm{kcal} / \mathrm{mol}$. For the latter, they are estimated in the range $0.5-1 \mathrm{kcal} / \mathrm{mol}$.

2b

Scheme 2

## $G$ and related scales

The $G$ scale was developed by Schleyer \& Allerhand [49]. It is based on the quantitative study of the solvent shifts undergone by the positions of the stretching vibrations, $\sigma$, of selected $\mathrm{X}=\mathrm{O}$ oscillators. These authors defined the $G$ scale through eqn (14):
a $G=\left(\sigma^{\mathrm{O}}-\sigma^{\mathrm{S}}\right) / \sigma^{\mathrm{o}}$
wherein $\sigma^{\mathrm{O}}$ and $\sigma^{\mathrm{S}}$, respectively, stand for the positions of the stretching vibration of $\mathrm{X}=\mathrm{O}$ in the gas phase and in solvent $S$. a is a constant characteristic of the probe (in [49a], eqn 14 had a misprint, corrected in [49b]). In the actual construction of the scale, these authors used the carbonyl stretching bands of N, N-dimethylformamide and benzophenone [50] and the sulfuryl band of DMSO [51]. These data were taken from the literature and, again, an averaging process was carried out.

Here we report the actual positions of the carbonyl vibrations for the various indicators, labeled $\sigma(\mathrm{CO}$, I), $\sigma(\mathrm{CO}, \mathrm{II})$ and $\sigma(\mathrm{SO})$. These data were obtained at 0.1 MPa but the working temperature (likely to be close to $25.0^{\circ} \mathrm{C}$ ) was not given in the original papers. The stated precision of the $\sigma$ values is $\pm 1 \mathrm{~cm}^{-1}$. Notice that, although the SI unit for $\sigma$ is $\mathrm{m}^{-1}$, we use $\mathrm{cm}^{-1}$ in the Table, as it has been customary in this field. In 1986, Somolinos, García and co-workers [52a] carried out a revision and extension of the $G$ scale. These authors also worked at 0.1 MPa at 'room temperature'. The scaling of their data is slightly different from that of [49]. Thus, the value for 1,2-dichloroethane $(G=95)$ was taken as an anchor point instead of that for dichloromethane $(G=100)$, the reason being the definite character of hydrogen bond donor of the latter. We also present these values in Table 2a.

Nicolet, Laurence \& Luçon published in 1987 a study on the solvent shifts undergone by the $\mathrm{C}=\mathrm{O}$ stretching band of methyl trichloroacetate, $\mathrm{CCl}_{3} \mathrm{COOMe}$ [53a]. This band has several features that make it particularly suitable as a molecular probe [53a]. Furthermore, as we discuss below, these solvent shifts can be combined with those for trichloroacetic acid, $\mathrm{CCl}_{3} \mathrm{COOH}$, in the same solvents to generate a scale of hydrogen bonding basicities [53a]. The experimental values are taken from [53a]. The positions were determined at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa and the stated precision is $0.5 \mathrm{~cm}^{-1}$. These values are listed as $\sigma(\mathrm{CO}$, III).

More recently, Kolling reported the position of the carbonyl stretching vibration of ethyl acetate [52b] and butanone [52c] (at 298.15 K and 0.1 MPa ) in a variety of solvents. Uncertainties on these data are given as $\pm 0.5 \mathrm{~cm}^{-1}$. These values are presented as $\sigma(\mathrm{CO}, \mathrm{IV})$ and $\sigma(\mathrm{CO}, \mathrm{V})$. Also reported are Notario's [52d] data on the carbonyl stretching band of ethyl acetate in a set of carefully purified solvents at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa . The corresponding positions $\left(\mathrm{in} \mathrm{cm}^{-1}\right)$ are listed as (CO, VI) and their uncertainties are estimated at $\pm 1 \mathrm{~cm}^{-1}$.

Prof. Laurence [53b] has suggested that in this study, a choice be made among the different IR-based scales. While we acknowledge the fact that at this moment there are 'too many' of them, we feel that the situation is not yet ripe for this choice to be made. There are two main reasons for this: (i) The data sets are fairly limited and it would be necessary to know more about the behavior of the various probes, and (ii) it might well be that the different scales show different sensitivities to the various components of the 'solvent effect'. In particular, there is no proof of the precise equivalence of all rankings of 'polarity' defined by means of these probes. It is to be hoped that this situation prompts further experimental research in the field.

## Scales of dipolarity-polarizability

These scales are based on the concept that solvent-solute interactions can be decomposed into 'general' and specific interactions [1]. The former have electrostatic and dispersive origins and can be related (at least conceptually) to reaction field theories. Specific effects include hydrogen-bonding and/or donoracceptor interactions. The term 'dipolarity' was coined by Kamlet, Abboud \& Taft (KAT) [2,54] in order to distinguish the interactions originating essentially in electrostatic effects from the 'overall' interactions included in Reichardt's concept of 'polarity'. It is obvious that this is somehow an oversimplification and that 'multipolar' is certainly more appropriate.
$\pi^{*}$
This scale was defined by KAT in 1977 [54]. It was intended to provide a quantitative measure of the
nonspecific part of van der Waals [17a] interactions between solvents and solutes. Operationally, the scale was based on the treatment of the solvatochromic shifts undergone by selected absorption bands of a variety of 'molecular probes'. These probes were aromatic molecules, mostly of the A- $\mathrm{C}_{6} \mathrm{H}_{4}-\mathrm{D}$ type (structures 3a and 3b), where A and D, respectively, stand for electron-acceptor (such as CN or $\mathrm{NO}_{2}$ ) and electron-donor (such as OMe or $\mathrm{NEt}_{2}$ ) groups (Scheme 3).
(a)

(b)

## Scheme 3

Experimentally, the following had been found for these compounds: (i) The frequency of the longest wavelength electronic absorption transition is solvent-dependent; (ii) Whenever specific interactions (such as hydrogen bonding) are excluded, medium effects on the frequencies of the solvatochromic bands of any two indicators are linearly related to a high degree of precision. Thus, consider two indicators, for example 1 and 2 , and let $\sigma(1)_{\mathrm{S} 0}$ and $\sigma(2)_{\mathrm{S} 0}$ stand for the positions of the maxima of their solvatochromic bands in a given reference solvent, $\sigma(1)_{\mathrm{S}}$ and $\sigma(2)_{\mathrm{S}}$ being the corresponding values in solvent S under scrutiny, eqn 15 was found to hold:
$\sigma(2)_{\mathrm{S}}-\sigma(2) \mathrm{S} 0=\mathrm{s}\left[\sigma(1)_{\mathrm{S}}-\sigma(1)_{\mathrm{S} 0}\right]$
where s is a constant dependent solely on 1 and 2 .
Given a solvatochromic indicator, the $\pi^{*}$ value for a solvent S was defined through eqn 16:
$\pi^{*}(\mathrm{~S})=\left[\sigma(\mathrm{S})-\sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)\right] /\left[\sigma(\mathrm{DMSO})-\sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)\right]$
where the $\sigma(\mathrm{S})$ pertain to the frequencies of the maximum of the solvatochromic band in the various solvents. $\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}$ (cyclohexane) and DMSO (dimethyl sulfoxide) were used as references by taking $\pi^{*}\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)=0$ and $\pi^{*}(\mathrm{DMSO})=1$ by definition.

The actual $\pi^{*}$ values for 57 nonhydroxylic solvents (but including some weakly hydrogen-bond donors such as chloroform, dichloromethane and nitromethane) were initially reported by KAT [54]. These values were arrived at by simultaneously solving eqns 15 and 16 for seven 'primary' indicators in this set of solvents. This original set of values was later extended by incorporating new data originating in new experimental work by the KAT group and in studies by Bekarek's [55] and Carr's [56] groups. Seven $\pi^{*}$ values were estimated by means of correlation eqns between $\pi^{*}$ and functions of $n$ and $\varepsilon_{\mathrm{r}}$. A database of $101 \pi^{*}$ values was thus constructed and published in 1983 [57]. This set has been extensively used over the years and is reported here.

In 1986 Laurence \& Nicolet [58] published a careful re-examination of temperature and medium effects on the solvatochromic bands of several of the most important indicators used in KAT's original construction of the $\pi^{*}$ scale. For our purposes, the following of their findings are particularly relevant: (1) The solvatochromic band of the indicator 4-(diethylamino)-nitrobenzene (4) (the single most widely used indicator in the KAT formalism) has a significant vibrational structure leading to a solventdependent band shape. (2) $\pi^{*}$ values are somewhat solute-dependent. Clearly, the precision of eqn 15 is not as high as initially believed. (3) Furthermore, it was clearly shown that for a given indicator, $\pi^{*}$ values are temperature-dependent ('thermosolvatochromism').

In a Thesis presented in 1991, M. T. Dalati [17b] reported the frequencies of the solvatochromic bands of 4-methoxynitrobenzene (5) and 4-(dimethylamino)-nitrobenzene (6) in 276 solvents at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa .6 was selected because previous studies had shown that its UV-visible spectrum is not appreciably affected by band shape problems. The solvatochromic band of 5 keeps a constant Gauss-Lorentz band shape all the way from the gas phase to the most polar solvents. A substantial part of these data, together with some new values obtained under the same experimental conditions were reported in 1994 [17a]. The corresponding frequencies of the absorption maxima are noted $\sigma_{\mathrm{NMe} 2}$ and $\sigma_{\mathrm{OMe}}$. The $\pi^{*}$ values obtained for each of these two indicators ( $\pi^{*} \mathrm{NMe} 2$ and $\pi^{*}{ }_{\mathrm{OMe}}$ ) by means of eqn 16 and the conditions $\pi^{*}\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)=0$ and $\pi^{*}(\mathrm{DMSO})=1$ are given in this compilation. Experimental uncertainties on the wavelengths of the absorption maxima can be estimated at $\approx 0.2 \mathrm{~nm}$. In some cases,
and because of spectral interferences $\sigma_{\mathrm{OMe}}$ values could not be determined experimentally and the values reported were obtained by interpolation using the corresponding $\sigma_{\mathrm{NMe} 2}$ values and the correlation between $\sigma_{\mathrm{NMe} 2}$ and $\sigma_{\mathrm{OMe}}$.

We draw attention to the fact that the $\pi^{*}$ scale was obtained as an average of experimental values for several indicators. This averaging process was aimed at smoothing out indicator-dependent structural effects and there is no doubt that averaging over seven different indicators introduces some degree of smoothing. On the other hand, from the standpoint of similarity, averaging blurrs the characteristics of the model. Inspection of $\pi^{*}, \pi^{*}{ }_{\mathrm{NMe} 2}$ and $\pi^{*}{ }_{\mathrm{OMe}}$ values shows that they are generally reasonably close but often show significant quantitative differences. The origin of some of these differences has been discussed in [17a]. It is essentially up to the reader to choose between an 'averaged' dipolaritypolarizability effect (that is, to use $\pi^{*}$ or an average of $\pi^{*}{ }_{\mathrm{NMe} 2}$ and $\pi^{*}{ }_{\mathrm{OMe}}$ ) or a scale based on a single indicator.

## SPP

This scale has been reported by Catalán and co-workers in 1995 [59]. Although it has not yet been used extensively, we include it in this compilation because it provides experimental data for 100 solvents, most of which are nonhydrogen bond donors or, eventually, very weak donors. Operationally, the scale is based on the solvatochromic shifts undergone by the long wavelength absorption maximum of two indicators: 2-(dimethylamino)-7-nitrofluorene (DMANF, 7) and 2-fluoro-7-nitrofluorene (FNF, 8). Experimental uncertainties on the wavelengths of the absorption maxima are $\approx 0.2 \mathrm{~nm}$ (Scheme 4).

7

8

## Scheme 4

These indicators are structurally related to those used in the construction of the $\pi^{*}$ scale. Their solvatochromic bands are also characterized by substantial bathochromic shifts with increasing dipolarity-polarizability of the solvent. The experimental positions (in $\mathrm{cm}^{-1}$ ) for the absorption maxima of both indicators, respectively $\sigma_{\mathrm{DMANF}}$ and $\sigma_{\mathrm{FNF}}$ are given in the compilation. Catalán et al. assume that band-shape effects are the same for both indicators and that they cancel out in the difference $\Delta \sigma$ $=\sigma_{\mathrm{DMANF}}-\sigma_{\mathrm{FNF}}$. Accordingly, for a given solvent S , the value of the 'solvent polarity-polarizability' parameter $\operatorname{SPP}(\mathrm{S})$ is defined through eqn 17:
$S P P(\mathrm{~S})=\left[\Delta \sigma(\mathrm{S})-\Delta \sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)\right] /\left[\Delta \sigma(\mathrm{DMSO})-\Delta \sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)\right]$
This implies the same normalization for both the $S P P$ and the $\pi^{*}$ scales.
Catalán et al. have set forth a scale with a different normalization $\left(S P P^{\mathrm{N}}\right)$ wherein the origin is not $\Delta \sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)$ but rather the calculated value of $\Delta \sigma($ gas $)$. The scales $S P P$ and $S P P^{\mathrm{N}}$ are given in this compilation. At this point, the only source of data for these scales is [59].
$\pi^{*}{ }_{a z o}$
These parameters have been defined by Buncel \& Rajagopal [61a]. Operationally, they are based on the solvatochromic shifts undergone by the longest wavelength absorption band ( $n \rightarrow \pi^{*}$ and $\pi \rightarrow \pi^{*}$ transitions) of a set of six azo merocyanine dyes $(\mathbf{9}-\mathbf{1 4})$ (Schemes 5-7). The position of these maxima is in the region 440-590 nm, far away from the cut-off points of a very large number of solvents. In their study, Buncel \& Rajagopal examined the spectra of these indicators in solution in 29 different solvents. Out of these, 25 were either nonhydrogen bond donors or weak hydrogen-bond donors. The frequencies of the maxima were determined at $25.0^{\circ} \mathrm{C}$ and under 0.1 MPa and are given in the compilation. The corresponding frequencies $\sigma_{\max }(\mathbf{9})$ to $\sigma_{\max }(\mathbf{1 4})$ in the various solvents are linearly related to a very high
degree. That is, for these indicators, eqn 15 holds. Notice that, as in the case of the indicators used by KAT, the standard deviations of these mutual correlations are substantially larger than the experimental uncertainties. The solvatochromic shifts of these indicators were averaged by simultaneously solving eqn 15 for the all of them, as in the case of the construction of the $\pi^{*}$ scale. This finally led to the $\pi^{*}{ }_{\text {azo }}$ scale we report in this compilation. The $\pi^{*}$ azo values are also normalized with respect to $\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}$ and DMSO. It is important to notice that, as shown by Buncel \& Rajagopal, the quality of the correlations of medium effects on solute properties obtained using $\pi^{*}$ or $\pi^{*}$ azo are very close. However, when the solute is an azo compound, $\pi^{*}$ azo performs better than $\pi^{*}$ and the opposite holds for nitro compounds solutes. It is clear that, notwithstanding the averaging process, all these scales keep some 'model-dependent' specificity, however, small. Detailed discussions on this topic, as well as a general review on the $\pi^{*}$ azo scale are given in the 1990 review by Buncel \& Rajagopal [61b].

## Scheme 6

13

14

Scheme 7
$\pi^{*}{ }_{2}$
As indicated earlier, the empirical scales examined above simultaneously reflect two contributions: (1) The electrostatic interactions between the charge distribution of the solute and the permanent or induced dipoles (or higher multipoles) of the solvent and (2) the dispersive solvent-solute interactions. In all these scales, the contribution of the former factor is very important. Thus, they are most suitable for the study of properties of solutes which are also strongly affected by these electrostatic interactions. It is an experimental fact, however, that other properties follow a different pattern of solvent-dependence, largely determined by dispersive interactions. Abe [62] addressed the problem of developing empirical scales suitable for the study of these properties. He developed a scale $\pi^{*}{ }_{2}$ based on the solvatochromic shifts undergone by the long wavelength electronic absorption transitions of three indicators: naphthalene $\left(\mathrm{C}_{10} \mathrm{H}_{8}\right)$, anthracene $\left(\mathrm{C}_{14} \mathrm{H}_{12}\right)$ and $\beta$-carotene. The scale was normalized by taking $\pi^{*} 2=0$ for the the gas phase and $\pi^{*}{ }_{2}=1$ for $c-\mathrm{C}_{6} \mathrm{H}_{12}$ solvent. For any given solvent S , $\pi^{*}{ }_{2}(\mathrm{~S})$ was given by eqn 18: $\pi_{2}^{*}(\mathrm{~S})=[\sigma(\mathrm{S})-\sigma($ gas $)] /\left[\sigma\left(\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}\right)-\sigma(\right.$ gas $\left.)\right]$

The frequencies appearing in this equation are for the ${ }^{1} \mathrm{~L}_{\mathrm{b}}$ electronic transition of $\mathrm{C}_{10} \mathrm{H}_{8}$ solute. Abe observed that solvent effects on the frequency of the ${ }^{1} \mathrm{~L}_{\mathrm{a}}$ electronic transition of $\mathrm{C}_{14} \mathrm{H}_{12}$ are linearly related to a high degree of precision. This is a situation similar to that described by eqn 15. This correlation was used to generate $\pi_{2}^{*}$ values for solvents for which no naphthalene data were available. The frequencies of the absorption maxima of the longest wavelength electronic absorption transition of $\beta$ carotene behave analogously and data for this solute were used to further expand the scale and to obtain $\pi^{*}{ }_{2}$ values for tetrachloromethane and nonane. Abe's original $\pi^{*}{ }_{2}$ values are given in this compilation. It is important to realize that, through the use of correlations of the form of eqn 15 , this scale involves an averaging process. Also, the experimental database includes results obtained in different laboratories. As in the original paper, the $\pi^{*}$ values are given in the compilation with three decimal figures but it seems safer to round off to only two, particularly on account of the very small solvent sensitivity of the ${ }^{1} \mathrm{~L}_{\mathrm{b}}$ electronic transition of $\mathrm{C}_{10} \mathrm{H}_{8}$ and the built-in averaging process.

The solvatochromic band of $\beta$-carotene is in the visible region, far away from the cut-off points of a very large number of solvents. This is a distinct advantage with respect to $\mathrm{C}_{10} \mathrm{H}_{8}$ and $\mathrm{C}_{14} \mathrm{H}_{12}$ indicators. It is also much more sensitive to medium effects than the long wavelength absorption band of these compounds. This has prompted Abe and colleagues [66] to extend the study of the long wavelength absorption band of $\beta$-carotene to a wider set of solvents at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa . Their results are also presented in the compilation. Uncertainties on the wavelength of the absorption maximum in these solvents can be estimated at $\sim 0.2-0.3 \mathrm{~nm}$. Notice that the subscript 2 (as in $\pi^{*}{ }_{2}$ ) is extensively used for solute parameter scales and care must be exercised in order to avoid confusions.

## Basicity scales

These scales are intended to quantify the more specific solvent-solute interactions in which the solvent plays the role of an electron pair-donor (the solute obviously being an electron pair-acceptor). Such interactions are Lewis-type acid-base (or Lewis-type donor-acceptor) interactions in the classical sense. Other interactions involving some cationic centers have been observed, where the solvent can act as an electron pair donor towards the cation but the cation can also donate d-electrons into the bond to the solvent ( $\pi$-back donation). Such interactions are called soft-soft interactions.

Here we single out some widely used scales of hydrogen bonding and of 'hard' and 'soft' basicities of solvents. Hydrogen-bonding interactions can be considered as particular cases of 'hard' basicity.

It has been shown [67a] by means of Correlation Analysis techniques that the general, quantitative description of basicity requires at least two orthogonal descriptors, $\mathrm{F}_{1}$ and $\mathrm{F}_{2}$. It follows that one can envisage an infinite number of 'single parameter' basicity scales (very much as in the case of dipolaritypolarizability). It is an experimental fact, however, that in many cases, the relative weights of the contributions of $F_{1}$ and $F_{2}$ vary within very narrow limits. This allows the construction of scales of broad applicability.

## Hydrogen bonding (HB) basicity scales

‘ $\Delta \nu_{O D}$ ' $\left(\Delta \sigma_{O D}\right)$ and $B$

The great sensitivity of the O-H (or O-D) oscillators to hydrogen bonding has long been known as it was already used by Stanford and Gordy in 1940 [68] as a tool to quantify the Lewis basicity of molecules. In 1968, Kagiya, Sumida \& Inoue [69] determined the positions (in $\mathrm{cm}^{-1}$ ) of the O-D stretching band of monomeric methan $\left[{ }^{2} \mathrm{H}\right] \mathrm{ol}$ in a variety of solvents. These workers took the difference between the positions of the absorption maximum in solvent S and in benzene, $\Delta \sigma_{\mathrm{OD}}=\sigma(\mathrm{S})-\sigma\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)$ as a quantitative measure of the HBA character of these solvents. Notice that in all the studies relevant to this section the notation $\nu$ was used for the positions of the bands (in $\mathrm{cm}^{-1}$ ), instead of $\sigma$, the notation presently recommended by the IUPAC. The formal concentration of methan $\left[{ }^{2} \mathrm{H}\right] \mathrm{ol}$ in these experiments was $0.4 \mathrm{~mol} / \mathrm{L}$. Measurements were carried out at $18 \pm 3^{\circ} \mathrm{C}$ and under a pressure of 0.1 MPa . Uncertainties on the values of the shifts were estimated at $\pm 1 \mathrm{~cm}^{-1}$. The accuracy of the positions is probably in the range $2-3 \mathrm{~cm}^{-1}$. We report the experimental values as $\sigma_{\mathrm{OD}}(\mathrm{K})$. Several years later, Burden, Collier \& Shorter [70] carried out a revision and extension of this study. Working conditions were similar to those used in [69]. Accuracy and reproducibility were deemed to be better than $\pm 1 \mathrm{~cm}^{-1}$. The precision of the $\sigma_{\mathrm{OD}}$ values was estimated at $2-3 \mathrm{~cm}^{-1}$. The results of their study is presented as $\sigma_{\mathrm{OD}}(\mathrm{S})$. Notice that this study also reports some values remeasured by Kagiya. They have been included in the $\sigma_{\mathrm{OD}}(\mathrm{K})$ list.

Koppel \& Palm [13,71] defined a scale of Lewis basicity of solvents, $B$, through eqn (19): $B=\sigma_{\mathrm{OD}}(\mathrm{gas})-\sigma_{\mathrm{OD}}(\mathrm{S})$
wherein $\sigma_{\mathrm{OD}}(\mathrm{gas})$ and $\sigma_{\mathrm{OD}}(\mathrm{S})$ stand for the values of $\sigma_{\mathrm{OD}}$ in the gas phase and in solvent S. In the initial study the experimental data were taken from various sources. These values were revised by Shorter and co-workers on the basis of their study quoted above and are presented here as $B(\mathrm{KP}-\mathrm{S})$. In cases wherein revised values were not available, the original Koppel-Palm values are given.

## $B^{\prime}$

A few years after the definition of the $B$ scale, Koppel \& Paju [71] re-defined the scale $B$ of solvent Lewis basicity through eqn 20 :
$B=\Delta \sigma_{\text {PhOH }}{ }^{\mathrm{CCl} 4}=\sigma_{\text {PhoH }}{ }^{\mathrm{CCl} 4}-\sigma_{\text {PhoH } \cdots \mathrm{S}}{ }^{\mathrm{CCl} 4}$
$\Delta \sigma_{\mathrm{PhOH}}{ }^{\mathrm{CCl}}$ stands for the position (in cm ${ }^{-1}$ ) of the O-H stretching mode of monomeric phenol in tetrachloromethane solution. $\sigma_{\mathrm{PhOH}} \ldots \mathrm{S}{ }^{\mathrm{CCl}}{ }^{\mathrm{C}}$ is the position of the $\mathrm{O}-\mathrm{H}$ stretching mode of phenol within the $1: 1$ complex with molecule S in tetrachloromethane solution. It is important to observe that, as emphasized by Koppel \& Paju, '. . .representation of the solvent basicity parameters by eqn 20 is equivalent to the introduction of the postulate that base-induced shifts of the stretching frequencies of the $\mathrm{X}-\mathrm{H}$ band of the [hydrogen bond] donors in infinite dilution in inert media can also characterize the Lewis basicity of the corresponding pure bases as solvents'. This is an important caveat to consider in Correlation Analysis treatments of medium effects. For the sake of clarity we use the notation $B^{\prime}$ to avoid possible confusions with the $B$ scale defined by means of eqn 19. In this compilation we report data from [71]. These data actually originate in a variety of sources and are noted $B^{\prime}(\mathrm{K}-\mathrm{P})$. It is quite difficult to assess the uncertainties in these values. On the basis of a comparison with data by Pickering, determined under the same experimental conditions, one can reasonably assume an average uncertainty of $\pm 4 \mathrm{~cm}^{-1}$ for these parameters. Data determined in 1984 by Makitra and co-workers [72] have also been included as $\mathrm{B}^{\prime}(\mathrm{K}-\mathrm{P})$ values. In his PhD work [73], Pickering carried out a careful study of the IR spectra of 1:1 HB complexes between phenol and a variety of bases. Working temperature and pressure were $25.0^{\circ} \mathrm{C}$ and 0.1 MPa . Calibration of the IR spectrometer was routinely performed. In a number of cases, e.g. in complexes involving carbonyl compounds, the observed associated band of hydrogen-bonded phenol is actually the envelope of two bands, corresponding to the interactions with the $n$ and $\pi$ electrons of the carbonyl group. Pickering was able to determine the maxima for each one of the two bands. When the deconvolution procedure was not required, the stated uncertainties are in the range of $\pm 2$ to $\pm 4 \mathrm{~cm}^{-1}$. We present the $\sigma_{\mathrm{OH}}$ values determined in this study as $\sigma_{\mathrm{OH}}(\mathrm{PS})$ (for Pickering \& Shorter). They are taken from [73]. The $B^{\prime}$ values derived through eqn 20 are given as $B^{\prime}(\mathrm{PS})$. With some significant exceptions the agreement with $B^{\prime}(\mathrm{K}-\mathrm{P})$ is reasonable (within $\pm 4 \mathrm{~cm}^{-1}$ ).

## $\beta$ scales

They are based on the concept of 'solvatochromic comparison method' (SCM) set forth by Kamlet \& Taft [2]. Consider a HB donor (HBD) (e.g. 4-nitrophenol) in solution in a solvent able to act as a HB acceptor (HBA). The overall medium effect on the frequency of the solvatochromic band of the indicator reflects both the 'general' (non-specific) solvent effect and the HB solvent-solute interaction. In order to unravel both contributions use is made of a second indicator, structurally very similar to the former (homomorph) but unable to act as an HBD (e.g. 4-methoxynitrobenzene). It is an experimental fact that the solvatochromic shifts undergone by both indicators on going from the gas phase to a variety of non-HBA solvents (or extremely weak ones) (say saturated hydrocarbons, perfluorinated compounds, etc.) are linearly related to a very high degree of precision. The first fundamental assumption of the SCM is that the same linear relationship holds for the nonspecific part of the solvent effect in the presence of HB. The second is that this contribution is proportional to the value of the $\pi^{*}$ parameter for the solvent S under scrutiny.

Consider the positions of the solvatochromic bands of the HBD indicator $i$, and its homomorph $j$ in solvent S , respectively $\sigma_{\mathrm{S}}(\mathrm{i})$ and $\sigma_{\mathrm{S}}(\mathrm{j})$. Equation 21 holds for non-HB solvents:
$\sigma_{\mathrm{S}}(\mathrm{i})=\mathrm{a}_{\mathrm{ij}} \sigma_{\mathrm{S}}(\mathrm{j})+\mathrm{b}_{i j}$
In the case of an HBA solvent, the experimental value of $\sigma_{S}(i)$ is significantly different from the value predicted by eqn 21 . The difference, $\Delta \sigma_{\mathrm{S}}(\mathrm{i})=\left[\sigma_{\mathrm{S}}(\mathrm{i})\right]_{\text {experimental }}-\left[\sigma_{\mathrm{S}}(\mathrm{i})\right]_{\text {eqn } 21}$ was taken as an operational measure of the HBA character of the solvent. In the initial work, the couples 4-nitrophenol(15)/4methoxynitrobenzene (5) and 4-nitroaniline/4-(diethylamino)-nitrobenzene were used. The $\beta$ scale of HB basicity was thus constructed on the basis of the scaled ( $\beta=0$ for $\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}$ and $\beta=1$ for HMPA) $\Delta \sigma_{\mathrm{S}}(\mathrm{i})$ values determined for these indicators. The database was further extended once it was realized that these 'solvatochromic betas' correlated to a high degree of precision with the logarithms of the equilibrium constants for the 1:1 HB associations between 4-fluorophenol ( $\mathrm{pK}_{\mathrm{HB}}$ scale) [2] or phenol [2] and a large number of bases in $\mathrm{CCl}_{4}$ solution. Excellent linear correlations were also found with the limiting ${ }^{19} \mathrm{~F}$ NMR shifts of 4-fluorophenol within these complexes $(\Delta)$ [2].

The initial set of published $\beta$-values was thus averaged over these five different properties [2]. Further extensions of the database were carried out as follows: First, data for a new set of three homomorphic couples were added to the initial set [74]. Later on, the SCM was applied in a somewhat 'looser' way: from the previous studies it was known that the nonspecific part of the solvatochromic shifts of the HBD indicators varied linearly with $\pi^{*}$ and, by definition, the HB contribution was taken as proportional to the value of the $\beta$ parameter. It follows that the positions $\sigma_{\mathrm{S}}(\mathrm{i})$ of indicator $i$ in a HBA solvent S can be expressed through eqn 22 wherein a and $b$ are constants:
$\sigma_{\mathrm{S}}(\mathrm{i})=\sigma_{\mathrm{c}-\mathrm{C}_{6} \mathrm{H}_{12}}(\mathrm{i})+\mathrm{a} \pi^{*}+\mathrm{b} \beta$
Equation 22 was first tested for several HBD indicators using a number of solvents for which both $\pi^{*}$ and $\beta$ values were available and then, applied to calculate new $\beta$ values for solvents for which only the $\pi^{*}$ values were known. All the data obtained in these studies, together with some more values determined by the methods indicated above were published in the 1983 review [57]. They are presented in the compilation under the heading $\beta$. An extremely detailed description of the methods used for the determination of these parameters is given in the 1981 review by KAT [2].

The SCM concept behind the determination of the $1983 \beta$ values was clearly defined but the averaging process involving several homomorphic couples somewhat blurred the model. The averaging of data determined directly by the SCM with results involving Gibbs energies of formation of $1: 1$ complexes in inert media, NMR shifts and values obtained through the use of eqn 22 essentially eliminated the model process. This notwithstanding, these $\beta$ values enjoyed a widespread use and have been proven useful in many cases.

As indicated earlier, in their first study of solvatochromic indicators, Nicolet and Laurence [75] showed that 4-(dimethylamino)-nitrobenzene(6) is a better indicator than 4-(diethylamino)-nitrobenzene. Furthermore, in a series of experiments performed on carefully purified and dried solvents at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa , they were able to compare the homomorphic couples 4-nitrophenol(15)/4-methoxynitrobenzene $(\mathbf{5})$ and 4-nitroaniline(16)/4-(dimethylamino)-nitrobenzene(6). These workers confirmed, under
more stringent experimental conditions, that in the absence of HB interactions, the linear relationship between the positions of the homomorphic indicators (that is, the very basis of the SCM) holds to an extremely high degree of precision. They selected the gas phase, perfluoroalkanes, $\mathrm{Me}_{4} \mathrm{Si}$, alkanes, $\mathrm{CCl}_{4}$, $\mathrm{C}_{2} \mathrm{Cl}_{4}$, polyhalogenated benzenes and 1,2-dichloroethane as a reference set of media to which they added the very weak HBA monohalobenzenes and 1,2,3-trichlorobenzene and the very weak $\mathrm{HBD} \mathrm{CH}_{2} \mathrm{I}_{2}$ and $\mathrm{HClC}=\mathrm{CCl}_{2}$. The number of data points was extended by using data determined at various temperatures (thermosolvatochromic method). The correlation eqns they obtained were as follows:
$\sigma(\mathbf{1 5})=1.0434 \sigma(\mathbf{5})-0.57 \mathrm{~cm}^{-1}$
$n=74 ; r=0.9980 ; \mathrm{u}=80 \mathrm{~cm}^{-1}$
$\sigma(\mathbf{1 6})=0.9841 \sigma(\mathbf{6})+3.49 \mathrm{~cm}^{-1}$
$n=99 ; r=0.9969 ; \mathrm{u}=115 \mathrm{~cm}^{-1}$
We report in this compilation the values of $\sigma(\mathbf{1 6})$ and $\sigma(\mathbf{1 5})$ determined by these workers. Then, by strictly applying the SCM to each homomorphic couple, we determined the $\beta$ values for all the solvents for which data were available. These results are presented as $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$ values. Operationally, they were computed as indicated in eqs 25 and 26 :
$\beta_{\mathrm{OH}}=-\Delta \sigma(\mathbf{1 5}-\mathbf{5}) /\left(2000 \mathrm{~cm}^{-1}\right)$
$\beta_{\mathrm{NH} 2}=-\Delta \sigma(\mathbf{1 6}-\mathbf{6}) /\left(2759 \mathrm{~cm}^{-1}\right)$
wherein
$-\Delta \sigma(\mathbf{1 5}-\mathbf{5})=[1.0434 \sigma(\mathbf{5})-0.57]-\sigma(\mathbf{1 5})$
$-\Delta \sigma(\mathbf{1 6}-\mathbf{6})=[0.9841 \sigma(\mathbf{6})+3.49]-\sigma(\mathbf{1 6})$
The values $2000 \mathrm{~cm}^{-1}$ and $2759 \mathrm{~cm}^{-1}$ in eqns 25 and 26 originate in the choice of hexamethylphosphoramide as a reference value ( $\beta=1$ for this solvent). In this medium, $-\Delta \sigma(\mathbf{1 5 - 5})=2000 \mathrm{~cm}^{-1}$ and $-\Delta \sigma(\mathbf{1 6 - 6})=2759 \mathrm{~cm}^{-1}$.

It is important to emphasize that in the initial studies many more values had been obtained using the couple 16/4-(diethylamino)-nitrobenzene than $\mathbf{1 5 / 5}$. The reason for this is that the absorption bands of the former couple are found at longer wavelengths. This situation turned out to be unfortunate for two reasons: (1) The effects of vibronic structure of the solvatochromic band of 4-(diethylamino)nitrobenzene, already discussed above. (2) Two features of $\mathbf{1 6}$ as a HBD: (i) with respect to $\mathbf{1 5}$, it is a much weaker HB acid. Thus, it is possible that in the case of very feebly basic solvents a sizable fraction of $\mathbf{1 6}$ remains unassociated [76] and (ii) $\mathbf{1 6}$ has two 'acidic' hydrogens. It is known that the strength of the second hydrogen bond is affected by both the acidity of the HBD and the stability of the first hydrogen bond [77]. Even if 4-(diethylamino)-nitrobenzene is replaced by $\mathbf{6}$, the latter two effects are unavoidable. In the Nicolet-Laurence work, extremely thin cells were used in order to allow the study of a large number of solvents having cutoff regions in the very near-UV region. This allowed the determination of a very large number of $\beta_{\mathrm{OH}}$ values. Also, the temperature was carefully kept constant at $25.0^{\circ} \mathrm{C}$. This was not the case in the determination of the original set of $\beta$ values. A direct, stringent comparison of $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$ was then possible. This comparison showed that, while the HBA rankings defined by these parameters are indeed roughly similar, the linear relationship between $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$ is family dependent. Family dependence was also found [76] when comparing $-\Delta \sigma(\mathbf{1 5 - 5})$ and $-\Delta \sigma(\mathbf{1 6 - 6})$ to the other properties included in the averaging processes that led to the construction of the 1983 database [57]. Of course, this detailed information was not available at the time the $\beta$ scale was constructed. As indicated earlier, at least two factors are needed to describe the 'basic' behavior of solvents. Different HBA scales are likely to involve different 'blends' of these factors and hence originate this family dependence. At this point it is unclear whether the behavior of $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$ stems from a different blend of factors or is simply a consequence of the low HB acidity of $\mathbf{1 6}$ or of its having two acidic hydrogens. In any case, the $\beta$ scale of choice at this point is $\beta_{\mathrm{OH}}$. Use of $\beta_{\mathrm{NH} 2}$ and the original $\beta$ should be reduced to a minimum.

This scale was developed by Catalán et al. in 1996 [78]. It is based on the application of the SCM to the couple of homomorphs 5-nitroindoline (17, NI) and 1-methyl-5-nitroindoline (18, MNI). Let $\sigma(\mathbf{1 7})$ and
$\sigma(\mathbf{1 8})$ be the positions of the longest wavelength absorption band of $\mathbf{1 7}$ and 18 in the UV-visible region. The authors consider the difference $\Delta \sigma=\sigma(\mathbf{1 7})-\sigma(\mathbf{1 8})$ to be a quantitative measure of the HBA character of the solvent. The value of the normalized parameter $S B$ ('solvent basicity') for any given solvent is defined through eqn 29:
$S B=[\Delta \sigma($ solvent $)-\Delta \sigma($ gas phase $)] /[\Delta \sigma($ TMG $)-\Delta \sigma($ gas phase $)]$
$\Delta \sigma$ (gas phase) was obtained by extrapolation of the $\Delta \sigma$ values for $n$-alkanes. TMG is tetramethylguanidine (the solvent leading to the largest HB basicity effects in their study).

Probes 17 and 18 absorb in a region of the UV-visible range that is, well removed from the cut-off region of most common solvents.

Values of $S B$ for 201 solvents, including a number of HBD materials were determined. The estimated uncertainty on the wavelengths of each of the various experimental absorption maxima was estimated at $\pm 0.2 \mathrm{~nm}$.

A very important fact is the high degree of similarity between $S B$ and $\beta_{\mathrm{OH}}$. [78] More precisely, with the only exception of the datum for pyridine, $S B$ and $\beta_{\mathrm{OH}}$ correlate to a very satisfactory degree of precision. This suggests that at least, a significant part of the difference in the HB basicity rankings defined by $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$ originates in the fact that indicator $\mathbf{1 6}$ has two 'acidic' hydrogens. Not enough data are available that allow to rule out some degree of family dependence.

Last we notice that aliphatic and alicyclic hydrocarbons, perfluorohexane and tetrachloromethane, have small but finite $S B$ values, some of which are comparable to that of benzene, for example. This does not imply that this study of indicators $\mathbf{1 7}$ and $\mathbf{1 8}$ is revealing any HB acceptor character of these materials (although other techniques are able to do so). The situation originates in the definition of $\Delta \sigma$. Thus, for the very same set of not HBA solvents, a direct comparison of $\sigma(\mathbf{1 7})$ and $\sigma(\mathbf{1 8})$ leads to eqn 30 :
$\sigma(\mathbf{1 7})=1.027 \sigma(\mathbf{1 8})+7.32 \times 10^{2} \mathrm{~cm}^{-1}$
$n=22, r=0.9995, \mathrm{u}=28 \mathrm{~cm}^{-1}$
The value of u is quite comparable to the experimental error. If departures of $\sigma(\mathbf{1 7})$ from the behavior prescribed by eqn 30 are used to quantify HB effects, as in the original SCM, these solvents appear as essentially devoid of HB basicity, in agreement with the behavior of $\beta_{\mathrm{OH}}$ and $\beta_{\mathrm{NH} 2}$.

## $\sigma_{C O}$ and $\Delta \sigma_{C O}$

As indicated above, Nicolet, Laurence \& Luçon published in 1987 a study on the solvent shifts undergone by the $\mathrm{C}=\mathrm{O}$ stretching band of methyl trichloroacetate, $\mathrm{CCl}_{3} \mathrm{COOMe}$ and trichloroacetic acid [53], $\mathrm{CCl}_{3} \mathrm{COOH}$. The latter is a strong HBD endowed with important properties: (1) Operationally, the formation of a complex $\mathrm{CCl}_{3} \mathrm{COOH} \cdots \mathrm{B}$ leads to a significant lowering of the values of the carbonyl stretching frequencies. (2) The dimerization constant of $\mathrm{CCl}_{3} \mathrm{COOH}$ is smaller than that of acetic acid. (3) The $\mathrm{C}_{3 \mathrm{v}}$ symmetry of the $\mathrm{Cl}_{3} \mathrm{C}$ group precludes the appearance of rotamers in the region of the $\mathrm{C}=\mathrm{O}$ stretching vibrational range. (4) This compound does not show the Fermi resonance phenomenon usual for carbonyl oscillators. Hence, the $\mathrm{C}=\mathrm{O}$ stretching band is sharp and symmetrical.

These authors studied the couple $\mathrm{CCl}_{3} \mathrm{COOMe} / \mathrm{CCl}_{3} \mathrm{COOH}$ in a way formally similar to the SCM , namely the 'IR Comparison Method'. Its foundations are as follows: (1) For solvents which are non-HBA or extremely weak HBA and the gas phase, the positions of the $\mathrm{C}=\mathrm{O}$ stretching bands of both compounds are linearly related to a high degree of precision, eqn 31:
$\sigma\left(\mathrm{CCl}_{3} \mathrm{COOH}\right)=1.1715 \sigma\left(\mathrm{CCl}_{3} \mathrm{COOMe}\right)-292.8 \mathrm{~cm}^{-1}$
$\quad n=11, r=0.9993, \mathrm{u}=0.26 \mathrm{~cm}^{-1}$
(2) The HB basicity of a HBA solvent is given by the difference, $\Delta \sigma\left(\mathrm{CCl}_{3} \mathrm{COOH}\right)$, i.e. between the experimental value of $\sigma\left(\mathrm{CCl}_{3} \mathrm{COOH}\right)$ and the value calculated by means of eqn 29 . We present in this compilation both series of values. They are taken from [53] and were determined at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa .

Notice that the experimental resolution of the experiments is $\approx 0.5 \mathrm{~cm}^{-1}$. The standard deviation of fit in eqn 31 is of the order of the experimental uncertainty. This is extremely satisfactory and leads us to hope that if more data become available in the future, $\Delta \sigma\left(\mathrm{CCl}_{3} \mathrm{COOH}\right)$ may well become one of the choice single parameter scales of HB basicity.

## Lewis basicities

These scales are intended to provide quantitative measures of the electron-donor ability of solvents, either as bulk materials or as single molecules involved in 1:1 donor-acceptor interactions.
$D_{s}$
This scale was defined by Persson, Sandström \& Goggin [79] in 1986. It is based on the shifts undergone by the position of the symmetric $\mathrm{Hg}-\mathrm{Br}$ stretching vibration in mercuric dibromide, $\mathrm{HgBr}_{2}$, on going from the gas phase to the solvent under scrutiny. It is quantitatively defined through eqn 32 :
$D_{\mathrm{s}}=\sigma_{\mathrm{Hg}-\mathrm{Br}}($ gas $)-\sigma_{\mathrm{Hg}-\mathrm{Br}}($ solvent $)$
$\mathrm{HgBr}_{2}$ is a 'soft' Lewis acid.
These values were determined by means of Raman spectroscopy (notice the total symmetry of the vibration). Uncertainties on $\sigma$ values can be estimated at $\approx 1 \mathrm{~cm}^{-1}$. The $\sigma$ values were determined at a temperature close to $25.0^{\circ} \mathrm{C}$. We report in this compilation the $D_{\mathrm{s}}$ values taken from [79a]. Notice that the $\sigma_{\mathrm{Hg}-\mathrm{Br}}$ (solvent) scale upon which the scale is based reflects both the 'soft' and 'hard' basicities of the solvent [79b] as well as, in principle, 'general' or reaction field effects. As pointed out by Marcus [79c], fairly high concentrations of $\mathrm{HgBr}_{2}(\approx 0.2 \mathrm{~m})$ are needed in these studies, exceeding the solubility of this compound in many useful solvents.

## $\mu_{M}$

This scale was developed by Marcus [80]. It is intended to provide an alternative means for determining the 'softness' of the solvent. Its definition, basic hypotheses and physical meaning are taken directly from Marcus' 1987 paper: 'Since water (W) is a 'hard' solvent, the standard molar Gibbs energy of transfer of ions from a reference solvent to other solvents (S), $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$, should depend on the softness of these solvents in a different manner for hard or soft ions. Other things being equal, hard ions should prefer water and soft ones the softer ones. Among the 'other things' that should be equal are the charge and the size of the ions, since these properties affect the value of $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$ greatly'.

Most of the data on this quantity available in the literature pertain to univalent ions, and among these the softest is $\mathrm{Ag}^{+}$. The size of this ion does not match exactly any hard univalent cation, but it is intermediate between those of $\mathrm{Na}^{+}$and $\mathrm{K}^{+}$. Hence, it is expedient to compare the value of $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$ for $\mathrm{Ag}^{+}$with the mean of $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$ values for $\mathrm{Na}^{+}$and $\mathrm{K}^{+}$. The result is the basis of the softness scale $\mu_{\mathrm{M}}$ (for malakos, soft in Greek), defined as follows eqn 33:
$\mu_{\mathrm{M}}=\left\{\left[\frac{1}{2}\right]\left[\Delta_{\mathrm{t}} G^{\circ}\left(\mathrm{Na}^{+}, \mathrm{W} \rightarrow \mathrm{S}\right)+\Delta_{\mathrm{t}} G^{\circ}\left(\mathrm{K}^{+}, \mathrm{W} \rightarrow \mathrm{S}\right)\right]-\Delta_{\mathrm{t}} G^{\circ}\left(\mathrm{Ag}^{+}, \mathrm{W} \rightarrow \mathrm{S}\right)\right\} / 100$
The sign of the expression is chosen so as to make $\mu_{M}$ more positive the softer the solvent $S$ is, and the division by 100 (for values of $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$ expressed in $\mathrm{kJ} / \mathrm{mol}$ ) serves to bring the values of $\mu_{\mathrm{M}}$ to a similar magnitude as other property indices of solvents used in linear solvation energy relationships, i.e. approximately between 0 and 1.'

Notice that in Marcus' original work, the 'softness' parameter was represented by $\mu$. Here we use $\mu_{M}$ in order to avoid any confusion with the modulus of the molecular dipole moment. We present in Table 2d the values of $\mu_{\mathrm{M}}$ taken from two papers by this author, [80,81]. They have been carefully checked against a list he kindly provided to us.

As regards the precision of the $\mu_{M}$ values, they were estimated by Marcus at $\pm 0.03$. Of course, this uncertainty is determined by the uncertainty on the experimental values of $\Delta_{\mathrm{t}} G^{\circ}(\mathrm{W} \rightarrow \mathrm{S})$.

Notice that, because of the definition of $\mu_{\mathrm{M}}$ as a difference of terms, individual contributions from cavity terms are likely to be reduced to a minimum.

## SP

In 1988, Gritzner [82a] defined the value of the 'softness parameter' $S P$ for a solvent S on the basis of eqn 34:
$S P(\mathrm{~S})=25+\left|\Delta_{\mathrm{t}} G^{\circ}(\mathrm{BCN} \rightarrow \mathrm{S})\right|$
The units of $S P$ are $\mathrm{kJ} / \mathrm{mol} .\left|\Delta_{\mathrm{t}} G^{\circ}(\mathrm{BCN} \rightarrow \mathrm{S})\right|$ is the absolute value of the standard Gibbs energy change
pertaining to the transfer of $\mathrm{Ag}^{+}$from benzonitrile to solvent S . The addition of $25 \mathrm{~kJ} / \mathrm{mol}$ and the use of the absolute value of $\left|\Delta_{\mathrm{t}} G^{\circ}(\mathrm{BCN} \rightarrow \mathrm{S})\right|$ are intended to yield positive values in all cases.

In a study published in 1993 [82b], he reported additional $\left|\Delta_{\mathrm{t}} G^{\circ}(\mathrm{BCN} \rightarrow \mathrm{S})\right|$ values. He also carried out a careful comparison of the results obtained by means of different experimental methods and established that, in general, they agree within $6 \mathrm{~kJ} / \mathrm{mol}$. It is only in a few instances that differences reach $7-9 \mathrm{~kJ} / \mathrm{mol}$. This suggests that the average uncertainties on $\mu_{M}$ are probably closer to $\pm 0.06$ (see above). It is important that the definitions of $\mu_{\mathrm{M}}$ and $S P$ easily allow the updating and extension of these magnitudes as this fundamental thermodynamic information becomes available. Here we report the actual $S P$ values given in [82a] and [82b].

We also draw attention to the concept set forth by Gritzner [79b] relative to the physical meaning of $S P$ : this parameter is essentially a measure of the interactions between soft acceptor solutes and soft solvents. Such interaction, which requires that both the acceptor solutes and the solvents contribute electron-pairs to the bond should be treated separately. According to this author, 'this type of interaction cannot be accounted for by solvent parameters such as the $\beta$ - and $B$-parameters, $D N$ and $\Delta H^{\circ}{ }_{\mathrm{BF} 3}$. Interactions of soft or hard solvents with solute acceptors which are not capable of undergoing soft-soft interactions can be described by solvent parameters accounting for the hard Lewis-donor properties of the solvents.

Notice that, in principle, the $S P$ scale also contains contributions from a purely electrostatic interaction between $\mathrm{Ag}^{+}$and the solvent.

## $D N$ and $\Delta H_{B F 3}^{\circ}$

The scale $D N$ ('donicity scale') was developed in 1966 by Gutmann [83] and has been extensively used since then. It precedes all other 'basicity scales' and has played a seminal role in solution chemistry. It is defined operationally as the negative of the standard enthalpy changes, $\Delta H_{S b C l 5}^{\circ}$ for the formation of the $1: 1$ adduct between antimony pentachloride and electron pair donor solvents D , both in dilute solution in 1,2-dichloroethane at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa , according to reaction 35:
$\mathrm{D}($ soln $)+\mathrm{SbCl}_{5}($ soln $) \rightleftarrows \mathrm{D}: \mathrm{SbCl}_{5}$ (soln)
$\Delta H^{\circ}{ }_{S b C l 5}$ is given by eqn 36:
$\Delta H_{S b C l 5}^{\circ}=\Delta H_{1}-\Delta H_{2}$
wherein $\Delta H_{1}$ and $\Delta H_{2}$ are the enthalpy changes under standard conditions for reactions 37 and 38 , respectively:
$\mathrm{D}($ pure liquid $)+\mathrm{SbCl}_{5}($ soln $) \rightleftarrows \mathrm{D}: \mathrm{SbCl}_{5}($ soln $)$
and
D (pure liquid) $\rightleftarrows \mathrm{D}($ soln $)$
All these data were determined by calorimetric techniques. In particular, $\Delta H_{1}$ was obtained by dissolving pure D into a solution containing an excess of $\mathrm{SbCl}_{5}$.

The $D N$ scale has been very widely used, particularly in the field of coordination chemistry.
Some significant shortcomings of this scale have been reported. A number of side-reactions, including reactions of basic impurities (notably water) have been described. Major anomalies have been reported for triethylamine and HMPA. Maria \& Gal [84] have published an extremely careful critical compilation of the available $D N$ values. Of great relevance are the results by Olofsson and co-workers [85]. They are numerous and seem to be very precise. These data are presented here together with their experimental uncertainties. The 'best' values (according to [84]) from Gutmann's work are also given.
$\Delta H^{\circ}{ }_{\mathrm{BF3}}$ has been defined by Maria \& Gal [84] as the standard enthalpy change for reaction [39], the formation of the $1: 1$ adduct between boron trifluoride and electron pair donor solvents D , both in dilute solution in dichloromethane at $25.0^{\circ} \mathrm{C}$ and 0.1 MPa :
$\mathrm{D}($ soln $)+\mathrm{BF}_{3}($ soln $) \rightleftarrows \mathrm{D}: \mathrm{BF}_{3}$ (soln)
The experimental method was discontinuous titration calorimetry. Reference [84] gives a succint description of the experimental method as well as a series of references to more detailed treatments of the
experimental methods. It seems that $\Delta H_{\mathrm{BF} 3}^{\circ}$ values are somewhat less likely to be affected by the same problems as the $D N$ numbers. The values reported in the compilation are taken from [84] and from Maria \& Gal's 1990 review [92]. The experimental uncertainties are generally below $1 \mathrm{~kJ} / \mathrm{mol}$ and are given in each case.
[Regarding the use of these scales: some members of the working party hold the view that, notwithstanding the great historical merits of $D N$, the scale of choice for actual correlation studies is $\Delta H_{\mathrm{BF} 3}^{\circ}$ and recommend that the use of $D N$ be discontinued. Other members put both sets of data on an equal footing of quality and practical usefulness. We feel that we should not enter this discussion. The user is advised to exercise great care when solvents pyridine, triethylamine and hexamethylphosphoric triamide are involved in the data set (see above). We feel that the best course of action is to use both scales and to carefully compare the results from the standpoints of the statistical quality and physical meaning. Needless to remind that these scales are related but different].
$D N$ and $\Delta H^{\circ}{ }_{\mathrm{BF} 3}$ are based on the interactions of dilute solutions of the relevant solvents in 1,2dichloroethane or dichloromethane with the reference substances $\mathrm{SbCl}_{5}$ and $\mathrm{BF}_{3}$. The underlying hypothesis involved in their use is the assumption that the quantitative ranking of 'donicity' they define also holds for the same compounds acting as solvents.

## STATISTICAL SCALES

These scales are in principle model-independent. They are constructed by statistically averaging medium effects on the physical properties or reactivity data of a wide number of solutes. Potential limitations are the very choice of the solutes and/or properties and eventually the definition of the 'subsidiary conditions' that link these scales to standard physical/chemical concepts. Of the various scales set forth so far we single out two families, because of their frequent use:

## $A$ and $B$

These scales were defined by Swain and co-workers in 1983 [93]. Their study involved 1080 data for 61 solvents and 77 reactions. They were analyzed according to the bilinear model described by eqn 40 :
$P(\mathrm{~S})=\mathrm{a} A(\mathrm{~S})+\mathrm{b} B(\mathrm{~S})+\mathrm{c}$
$P(\mathrm{~S})$ is the value taken by property $P$ in solvent $\mathrm{S} . \mathrm{a}, \mathrm{b}$ and c are constants depending only on the solute and the property under consideration. $A$ and $B$ are, respectively, the anion-solvating ('acity') and the cation-solvating ('basity') tendencies of $S$. The determination of $A$ and $B$ values was carried out from the statistical study of the database indicated above together with the following subsidiary conditions: $A=B=0$ for $n$-heptane, $A=B=1$ for water, $A=0$ for HMPA and $B=0$ for trifluoroacetic acid. The latter conditions are 'critical', in the sense that they involve mechanistic assumptions. The study involved both non-HB donors as well as HB donors. We present the available $A$ and $B$ values in Table 2d, together with their statistically determined uncertainties. The publication of these scales led to a substantial amount of controversy [1]. It is not appropriate to dwell on it, particularly since Prof. Swain is unfortunately no longer with us. However, we must caution the reader that, although the two scales $A$ and $B$ were constructed with the condition of being orthogonal, we find that for the solvents included in this study, that is, non-HB donors or very weak HB donors $A$ and $B$ are very strongly correlated: more precisely, if we take all the available values, $A$ and $B$ are correlated with a correlation coefficient of 0.72 . By excluding six solvents the correlation increases up to 0.93 . Under these conditions, it is clear that $A$ and $B$ fail to comply with the mathematical condition of orthogonality imposed on them and with the putative physical meaning they are supposed to convey.

## $S^{\prime}$

This scale was introduced by Drago in 1992 [94a]. It is based on the statistical treatment of 30 molecular probes and 31 solvents. The latter were chosen in order to avoid 'specific' solvent-solute interactions. Data were analyzed on the basis of the correlation eqn 41:
$\Delta \chi=S^{\prime} \mathrm{P}+W$
In this expression $\Delta \chi$ stands for the effect of the solvent on the physicochemical property under
consideration. $S^{\prime}$ stands for Drago's 'universal' descriptor of solvent polarity. P is a solute parameter intended to measure the susceptibility of the solute probe to polarity and $W$ a nonzero intercept at $S^{\prime}=0$. The scale was anchored by taking $S^{\prime}=3.00$ for DMSO. All the available $S^{\prime}$ values, as updated in [94c] are presented in Table 2d. The original data are given in [88a-c]. Unless reported otherwise, statistical uncertainties are generally taken as 0.01 on the basis of the reported values. $S^{\prime}$ essentially quantifies dipolar interactions (dipole-dipole, dipole-induced dipole) and because of the choice of the various probe systems, data for solvents of low dipolarity-polarizability are extremely scarce.

(a) Values, in $\mathrm{cm}^{-1}$, taken from [53]; (b) Values, in $\mathrm{cm}^{-1}$, taken from [79]; (c) Values taken from [79]; (d) Values taken from [80], unless noted otherwise; (e) Values taken from [82]; (f) Values, in kcal/mol, taken from [83] and collected in [36], unless noted otherwise; (g) Values, in $\mathrm{kJ} / \mathrm{mol}$, taken from [84]; (h) Values taken from [93]; (i) Values taken from [94]; (j) Value taken from a personal ommunication from Prof. Y. Marcus; (k) Value, in kcal/mol, taken from [86] and collected in [84]; (1) Value recommended in [84]; (m) Value taken from [81]; (n) Value, in kJ/mol, taken from [92]; (o) Value, in kcal/mol, taken from [87] and collected in [84]; (p) Limited data available; (q) Value, in $\mathrm{kcal} / \mathrm{mol}$, taken from [88] and collected in [84]; (r) Calculated from betaine shift only; (s) Value, in $\mathrm{kcal} / \mathrm{mol}$, taken from [90] and collected in [84]; (t) Value, in kcal/mol, taken from [89] and collected in [84]; (u) Value measured in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solution, at 218 K ; (v) Estimated from $v_{\mathrm{S}}(\mathrm{Hg}-\mathrm{I})$; (x) Value, in $\mathrm{kcal} / \mathrm{mol}$, taken from [91] and collected in [84].

## GENERAL COMMENTS ON THE SCALES

In general terms and as a first approximation, the electrostatic, nonspecific part of solvation can be described in terms of the orientation and polarization components of the reaction field. Dispersive interactions are also of fundamental importance. For practical purposes, the spirit of some of the criteria set forth by Koppel \& Palm [13] and Palm \& Palm [14] seem appropriate at this point. Thus, we consider the orientation component of the solvent polarization to be appropriately described by the function $\left[g\left(\varepsilon_{\mathrm{r}}\right)\right.$ $-f(n)]$ while the atomic and electronic polarization part, together with dispersive interactions, can be described by $f(n)$. Thus, for solvents such as those examined here, we can expect 'overall solvation' scales as well as 'polarity-polarizability' scales to be amenable to a treatment as linear combinations of these two functions. Thus, for the value taken in a given medium by any such scale, $S C$, eqn 42 is expected to hold:
$S C=\mathrm{a} f(n)+\mathrm{b}\left[g\left(\varepsilon_{\mathrm{r}}\right)-f(n)\right]+\mathrm{c}$
wherein $\mathrm{a}, \mathrm{b}$ and c are constants. We present in Table 3 the results of such a treatment. It is clear that the various scales presented here generally follow eqn 42 to a significant degree of precision. In the worst cases, removal of just a few data points leads to quite respectable correlation coefficients. Notice that the range of ratios $b / a$ is quite broad. This, of course, is one of the reasons behind the proliferation of scales over the years.

It is reasonable to suggest that any study of medium effects on a given property be carried out first using $f(n)$ and $\left[g\left(\varepsilon_{\mathrm{r}}\right)-f(n)\right]$ separately and then as linear combination of both and avoiding solvents in which substantial 'specific' interactions (hydrogen bonding and/or donor-acceptor effects) can be expected to be important on account of the nature of the solute and/or the property under scrutiny. Then, after consideration of the b/a ratio, the use of various empirical scales can be explored. Notice that in the case of the $\pi^{*}$ scale, some specific interactions involving polychlorinated and aromatic solvents are likely to be present. They are dealt with in the d $\delta$ formalism characteristic of this method [3].

As regards the scales of hydrogen bonding and Lewis basicities, we have selected $\beta_{\mathrm{OH}}$ as an appropriate reference in order to explore the mutual correlations of the other scales. As indicated earlier, two factors are needed in order to describe 'basicity'. Thus, in view of the relatively poor correlation between $\beta_{\mathrm{OH}}$ and $D_{\mathrm{s}}$ or $\mu_{\mathrm{M}}$, a preliminary exploration using these scales seems in order. This should allow to narrow the field of the search. It should be kept in mind that, very often, correlations of 'basicity' effects with any of the various single parameter basicity scales reported herein leads to a clear display of family dependence. This should not be overlooked, as it is physically important. Of course, care should be exercised when comparing very small data sets because chemically unsound results can be obtained.
(Regarding the correlations portrayed in Table 3b and 3c. Prof. Gritzner [79b] has expressed his concern about these correlations on account of the paucity of soft-soft systems in the general database. We feel that, in any case, these correlations are useful as they show the present statistical status of the matter. Of course, the reader should not use them without proper consideration of the physical meaning of the various scales. More extensive discussions of these problems, including discussion of data for hydroxylic solvents are given in [95].)

We conclude by reminding the reader that this compilation provides more scales and properties than generally used for the purpose of the treatment of 'medium effects'. One of the main reasons for this is the concept that scales and physical magnitudes should be selected considering their physical meaning and the similarity principle [15]. Appropriate choices would lead to a deeper understanding of the role of the solvent [96].

Table 3a Results of the correlations between different scales and the functions $f(n)$ and $\left[g\left(\varepsilon_{\mathrm{r}}\right)-f(n)\right]$. Correlations are in form: $y=a x+b$ and $z=a x+b y+c$

& \text { (excluding solvents \# 42, 112, 253, 303, 309 and 327) }
\end{aligned}
$$

## ACKNOWLEDGEMENTS

This work was supported by grants PB93-0289-C02-02, PB93-0142-C03-01, and PB96-0927-C02-01 from the Spanish D.G.E.S.

We are most grateful to Prof. C. Reichardt for his valuable advice and relentless moral support. We also thank Prof. M. F. Ruasse for her careful reading of the final version of the text and for a number of useful suggestions. This work is dedicated in memoriam to Drs M. J. Kamlet and R. W. Taft.

## APPENDIX

Some symbols, acronyms and abbreviations used in this text
DMANF 2-(dimethylamino)-7-nitrofluorene
DMSO dimethylsulfoxide
FNF 2-fluoro-7-nitrofluorene
HB Hydrogen bond
HBA Hydrogen bond acceptor
HBD Hydrogen bond donor
HMPA Hexamethylphosphorictriamide
KAT Kamlet, Abboud, Taft
MNI 1-methyl-5-nitroindoline
$n \quad$ number of data points (in correlations)
NI 5-nitroindoline
r correlation coefficient
SCM Solvatochromic comparison method
TMG Tetramethylguanidine
TMS Tetramethylsilane
u Standard deviation
