#### Abstract

A two-electron aromatic bis(tris-trimethylsilylmethylene)-substituted tetraborane(4) was found to be a useful precursor for the synthesis of two-electron aromatic tetraboranes(6), triboracyclopropanates, as well as tetraboranes(6) distorted toward triboracyclopropanates with boryl bridges. Bishomo two-electron aromatics with a borata bridge and a protonated borata bridge, respectively, are also presented.

## INTRODUCTION

Two-electron aromatics of types I-III [1-3] as well as those of types V-VII [4-6] are known experimentally, IV [7] and VIII [8] with three and four adjacent boron atoms, respectively, only from computations. The centers of all of these aromatics are connected by classical two-center-twoelectron(2c2e) $\sigma$-bonds. Two-electron aromatics with nonclassical $\sigma$-bonds, i.e., $\sigma$-electrons delocalized over more than two centers, have been postulated for $\mathbf{1}$, [9] the corner-protonated form of $\mathbf{I}$, on the basis of computations as early as 1980. The isoelectronic $\mathbf{2 u}$ [7] was computed in 1995 to be lower in energy than the classical $\mathbf{2} \mathbf{u}^{*}$ by not less than $54.9 \mathrm{kcal} / \mathrm{mol}$. As a first experimental approach to compounds of type 2, the boryl-bridged 2a was obtained recently by addition of 4-t-butylpyridine to the first repre-

[^0]sentative of two-electron aromatic tetraboranes(6) with nonclassical $\sigma$-bonds, $\mathbf{3}$ [10]. A first derivative of the corresponding two-electron aromatic tetraborane(4) 4 was also presented [11].

## RESULTS AND DISCUSSION

## Distorted rhomboid tetraboranes(4)

The recently described $\mathbf{3 a}$ [10] can be transformed into $\mathbf{4 a}$ by reaction with lithium naphthalenide in THF at $-100^{\circ} \mathrm{C}$ [12]. Tetraborane(4) 4b, a stereoisomer of $\mathbf{4 a}$, is obtained in low yield during the synthesis of $\mathbf{3 a}$.

4*

Due to a center of inversion, the $B_{4}$-ring of $\mathbf{4 b}$ is perfectly planar while that of $\mathbf{4 a}$ shows a folding angle of $177^{\circ}$. The lengths of the B-B edges of $\mathbf{4 b}$ [154.5(3) and $\left.179.0(3) \mathrm{pm}\right]$ are close to those of $\mathbf{4 a}$ [153.6(3), 179.1(3)], the short diagonal of $\mathbf{4 b}$ is slightly shorter [167.2(4) vs. 169.3(5)]. Obviously, four of the six electrons of the $\sigma$-skeleton in $\mathbf{4 a}, \mathbf{b}$ are mainly localized in the two short $\mathrm{B}-\mathrm{B}$ bonds. The remaining two electrons are delocalized over the four boron centers. This can be regarded as the consequence of strong hyperconjugation between formally empty p-orbitals in the plane of the B4 ring in classical $4^{*}$ with a $\sigma$-bond along the short diagonal. The ${ }^{11}$ B NMR chemical shifts of $\mathbf{4 b}$ ( 32 and 121 ppm ) are similar to those of $\mathbf{4 a}$ ( 33 and 125 ppm ). Attempts to determine the barrier of topomerization [12] of $\mathbf{4 b}$ failed due to low thermal stability of the latter.

## Triboracyclopropanates by addition of nucleophiles to tetraborane(4) (4a)

Reactions of $\mathbf{4 a}$ with lithiumamides, lithiumalkyls, or $\mathrm{NaBEt}_{3} \mathrm{H}$ lead to $\mathbf{2 b}, \mathbf{2 c}$ [13], or 2d, respectively, addition of 4-t-butylpyridine or 4-dimethylaminopyridine yields blue and red solutions of $\mathbf{2 e}$ and $\mathbf{2 f}$, respectively. All new compounds were characterized by NMR spectroscopy as well as by X-ray structural analyses. Relevant distances in $\mathbf{2 b} \mathbf{- 2 f}$ are compared in Table 1 to those computed for $\mathbf{2 g - i}$ and $\mathbf{2 u}$ at the B3LYP/6-31G* level.

Addition of nucleophiles transforms the four-membered two-electron aromatic $\mathbf{4 a}$ into threemembered two-electron aromatics $\mathbf{2 b} \mathbf{- 2 f}$. Compounds $\mathbf{2 b}$ and $\mathbf{2 c}$ are characterized by remarkably short B2-B3 distances of only 147.4 and 148.3 pm , respectively, the shortest B-B bonds ever observed. A
corresponding $B-B$ distance of 148.0 pm was calculated for the prototype $\mathrm{B}_{3} \mathrm{H}_{4}^{-}$anion $\mathbf{2 u}$ at MP2/6-31G* [7]. The B3-B4 distances in $\mathbf{2 b}$, 2c, and $\mathbf{2 g}$ ( 264,251 , and 264 pm ) differ considerably from those in $\mathbf{2 d}, \mathbf{2 e}$, and $\mathbf{2 f}(205,192$, and 200 pm ) which are close to that calculated for $\mathbf{2 i}$ (195.2 ppm). These findings can be explained by a strong interaction of the formally empty p-orbital at B4 in $\mathbf{2 d}, \mathbf{2 e}$, and $\mathbf{2 f}$ with the $3 \mathrm{c} 2 \mathrm{e} \sigma$-bond connecting B1, B2, and B3. This p-orbital is oriented close to orthogonal with respect to the axes of the p-orbitals of the aromatic $\pi$-system in $\mathbf{2 e}$ and $\mathbf{2 f}$ as seen from their B3, B1, B4, N torsional angles of 109 and $117^{\circ}$. The corresponding angles are considerably larger in $\mathbf{2 b}, \mathbf{2 d}$, and $\mathbf{2 c}\left(\mathrm{B} 3, \mathrm{~B} 1, \mathrm{~B} 4, \mathrm{X}=131,140\right.$, and $152^{\circ}$ ). The interaction of the p-orbital at B4 with the three-membered ring is considerably reduced in $\mathbf{2 b}$ by the amino donor at B 4 . This argumentation is supported by the even larger B3-B4 distance of 268 pm in a dianion [13] formally carrying a carbanionic donor at B 4 . In $\mathbf{2 c}$ the electronic effect of the alkyl substituent as well as steric hindrance probably reduce the interaction discussed above. Thus, strong interaction between an exocyclic boryl boron center and a negatively charged triboracyclopropane ring with a nonclassical $\sigma$-skeleton takes place in $\mathbf{2 e}, \mathbf{2 f}$, and $\mathbf{2 i}$. This interaction is considerably reduced in $\mathbf{2 b}$ and $\mathbf{2 g}$ where the formally empty p-orbital at the boryl boron is partly filled by strong donor substituents. Alternatively, conjugation can be cancelled by adding a hydride anion to the exocyclic boron: a B3-B4 distance of 280.3 pm is computed for $\mathbf{2 k}$. Our efforts for an experimental verification have been unsuccessful: addition of $\mathrm{NaBEt}_{3} \mathrm{H}$ to $\mathbf{2 d}$ does not lead to the desired product, but to the bishomo two-electron aromatic $\mathbf{5}$ discussed in the section "A bishomo two-electron aromatic with a borata bridge".

Computations on models $\mathbf{2 o}$ and $\mathbf{2 p}$ show that the orthogonal orientation of the boryl substituent is strongly preferred over the coplanar one. This observation is reminiscent of the results obtained for the dication of methylenecyclopropene [14]. In both cases, the 2 e -aromatics are poor $\pi$-electron donors due to their strong aromatic stabilization [15], but strong $\sigma$-electron donors due to ring strain.

## Tetraboranes(6) distorted toward triboracyclopropanates with boryl bridges

The tetraborane(6) $\mathbf{3 c}$ is obtained by addition of 3,5-di- $t$-butylaniline to $\mathbf{4 a}$. Protonation of $\mathbf{2 c}$ yields $\mathbf{3 d}$, while $\mathbf{3 e}$ is accessible from $\mathrm{Me}_{2} \mathrm{NSiMe}_{3}$ and $\mathbf{3 f}$, which can be prepared from $\mathbf{3 a}$ and $\mathrm{LiCH}_{2} \mathrm{SiMe}_{3}$. All compounds were characterized by NMR and X-ray structural analyses (see Table 2).

The geometrical details of the B1, B3, B4 triangle in 3c are similar to those of the corresponding triangle in $\mathbf{2 b}$. B4 of $\mathbf{3 c}$ is planar-tetracoordinate, while B2 shows a distorted tetrahedral coordination

3d

sphere and considerably longer distances to B1 and B3 than B4. Thus, $\mathbf{3 c}$ can be regarded as a two-electron aromatic with three adjacent boron atoms of type 2 , where the metal cation is replaced by an aminoboryl bridge. Computed distances for the model $\mathbf{3 u}$ are close to those determined for $\mathbf{3 c}$. Obviously, the amino substituent is responsible for the distortion of the tetraboranes(6) $\mathbf{3} \mathbf{c}$ and $\mathbf{3 u}$ toward structures of type $\mathbf{2}$. Interestingly, a comparable distortion is computed for $\mathbf{3} \mathbf{u}^{*}$ with the lone pair at nitrogen in the $\mathrm{B}_{4} \mathrm{~N}$ plane. Steric hindrance of a trimethylsilyl substituent in $\mathbf{3 d}$ leads to a similar but less pronounced distortion compared to 3c. In 3e, the amino-substituted boron is tetrahedrally distorted and has a long distance to B1.

[^1]
## A bishomo two-electron aromatic with a borata bridge

Addition of a hydride anion to $\mathbf{2 d}$ is a slow reaction which does not lead to a compound corresponding to $\mathbf{2 k}$ but to $\mathbf{5}$ instead. A related product $\mathbf{6}$ is obtained when $\mathbf{3 g}$ [10] is reacted with $\mathrm{NaBEt}_{3} \mathrm{H}$. Note that the stereochemistry of the trimethylsilyl substituents, which is different in the starting materials $\mathbf{2 d}$ and $\mathbf{3 g}$, is retained in the corresponding products 5 and $\mathbf{6}$.

5

6

7a

$3 g$

The formation of $\mathbf{6}$ can be easily explained in analogy to the transformation of Paetzold's 7b into $\mathbf{8}$ [16]. While 7b is first attacked by an electrophilic methyl iodide at the nucleophilic B-B bond drawn in bold, the corresponding B-B bond of $\mathbf{7 a}$ is attacked intramolecularly by a nearby proton. This generates one formal negative charge at the carbon to which it was bound. A new bond between the latter and a nearby boron forms and a bridging H becomes a terminal one in 6 . A similar transformation involving migration of a silyl group to a boron center must take place after hydride addition to $\mathbf{2 d}$. The transannular distances B3-B1 and B3-B2 in 5 and $\mathbf{6}$ (181.8, 175.6, and 175.3, 176.4, respectively) are shorter than any observed in anionic bishomo aromatics before [17]. To the best of our knowledge, $\mathbf{5}$ is the first homoromatic molecule with a borata bridge. Known homoaromatics contain familiar methylene bridges, which are isoelectronic to borata bridges. In contrast, the protonated form of such a bridge, which is found in $\mathbf{6}$ and in $\mathbf{7 b}$, is common in arachno and hypho boranes. This kind of a homo bridge completes the series of classical and nonclassical homo bridges [17] by a link in between: while clas-
sical and nonclassical homo bridges contain two two-center-two-electron(2c2e) bonds or one three-center-two-electron(3c2e) bond, respectively, the protonated borata bridge contains one $2 \mathrm{c} 2 \mathrm{e}-$ bond as well as one 3c2e-bond.

## CONCLUSION

In this paper, we report recent results in the chemistry of two-electron aromatics with nonclassical $\sigma$-skeletons built from three and four boron atoms. Two-electron aromatic triboracyclopropanates with a boryl substituent at the tetracoordinate boron center are obtained by addition of nucleophiles to an aromatic tetraborane(4). We present representatives of a class of molecules where $\sigma \rightarrow p$ interactions are considerably stronger than $\pi \rightarrow p$ interactions. The huge aromatic stabilization energy of two-electron aromatics like those of type 2 and ring strain in three-membered rings explain this unusual behavior. A strong tendency to form two-electron aromatics of type $\mathbf{2}$ is also observed in those compounds of type 3 which possess electronically or sterically active substituents. Intramolecular rearrangements of a tetraborane(6) dianion led to the first homoaromatic with a classical borata bridge.
